right-sided approach, the liver and gallbladder are packed away superiorly. When additional mobilization of the liver is required, the avascular right triangular ligament is incised. The posterior parietal peritoneum on the white line of Toldt is incised from the pelvis (region of the iliac artery) to the right upper quadrant (region of hepatic flexure). The anterior pararenal space is developed by dissecting in the plane between the anterior renal fascia and the mesentery of the ascending colon. With large inflammatory masses, the anterior pararenal space may be difficult to develop. It is important to avoid injury to the ascending mesocolon, since injury to the right colic and ileocolic arteries may devitalize this segment of colon. It is important to resect the renal fascia in its entirety for the best chance of surgical cure and to avoid any intra-abdominal tumor spillage.

After mobilizing the hepatic flexure of the colon using sharp and blunt dissection, the second part of the duodenum is mobilized medially using the Kocher maneuver (Fig. 60-26). With medially located tumors, mobilization of the duodenum should be performed with extreme care in order to avoid injury.

After mobilization of the duodenum, the IVC is identified posteriorly. Dissection anterior to the IVC will enable identification of the renal vein and gonadal vein (on the right side). Placement of a vessel loop will enable gentle traction of the renal vein. The renal vein is palpated for any tumor thrombus. Next the renal artery is identified posterior to the renal vein. If identification of the renal artery is difficult, attention is turned to the lower pole of the kidney to identify the ureter and gonadal vein. If technically feasible, the gonadal vein is spared. However, often because of the large size of the renal tumor, the gonadal vein cannot be safely left intact without the risk of avulsion from the IVC (right side) or left renal vein. With ligation of the ureter, the kidney is lifted from a posterior to an anterior position in order to aid in identification of the renal artery posterior to the kidney.

Another option for identifying the right renal artery in difficult hilar dissections is to dissect in the interaortocaval region at its takeoff from the aorta (Fig. 60-27). The right renal artery can be ligated with 0 silk suture or in emergent cases with a surgical clip. With the renal artery controlled, the right kidney and tumor will decrease in size and engorgement, easing the dissection of the kidney at the hilum and the remaining sites. The right renal vein, which should now be flaccid, is examined for any tumor thrombus and subsequently doubly ligated with 0 silk tie and 2-0 silk suture ligature and divided. Identification of the renal artery should be technically much easier lateral to the IVC, which can now be doubly ligated and divided. Attention should be given to the lumbar veins, which enter the IVC (Fig. 60-28 on the Expert Consult website). If avulsed, bleeding should be controlled with suture ligatures and not surgical clips since surgical clips do not provide adequate hemostasis for the lumbar veins. These veins can retract, thereby exacerbating the degree of retroperitoneal bleeding, which will be difficult to access and control.

Figure 60-28. Branches of the inferior vena cava (IVC) and aorta. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

For left radical nephrectomy, after incision of the white line of Toldt from the splenic flexure to the common iliac artery, the descending colon is reflected medially. The renocolic ligament is divided and extreme care is taken to avoid injury to the tail of the pancreas. The left renal vein is identified using the anterior surface of the aorta as a guide. The left renal artery is usually located cranial and posterior to the left renal vein. After further mobilization of the lower pole of the kidney, the left ureter and the left gonadal vein are identified. The left gonadal vein can be traced to its insertion to help identify the left renal vein. Depending on the size and location of the tumor, the surgeon determines whether the left gonadal vein should be left intact or tied off and transected to help with mobilization of the kidney. The ureter is divided, and the inferior and posterior surface of the kidney is mobilized to identify the left renal artery. Once the left renal artery and vein are identified, the renal artery is ligated with two right-angle clamps and divided. Preferably, the

Figure 60-27. The anteromedial surface of the inferior vena cava (IVC) can be used as a guide to identify the short right renal vein. The right renal artery is usually located deep to the right renal vein and is sometimes easier to identify in the interaortocaval groove. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

proximal end of the renal artery is clamped with two right-angle clamps and the distal end with one right-angle clamp. The renal artery is divided using a fine scalpel. The proximal end is ligated with 0 silk suture and further secured with 2-0 silk suture ligature; the distal end is tied with 0 silk tie. With the renal artery secured and divided, the renal vein is secured and divided in a similar fashion.

At times, the renal artery and vein may not be able to be separated individually because of significant hilar lymphadenopathy. Then, a whole-pedicle clamp technique may be utilized to control the hilar vessels (Fig. 60-29 on the Expert Consult website). While a risk of arteriovenous fistula may be associated with en bloc ligation of the whole renal pedicle (Lacombe, 1985), some small clinical series have not found any evidence of such fistulas in patients undergoing nephrectomy who have been managed by en bloc stapling of the renal hilum (Ou et al, 2008; Chung et al, 2013). The vascular pedicle is bluntly dissected until the pedicle has a 2- to 3-cm diameter. Long curved vascular clamps (e.g., Satinsky clamps) or renal pedicle clamps (e.g., Crawford, Young, Mayo) are used to clamp the renal artery and vein together. The pedicle is pinched and the first clamp is placed at the lowermost aspect of the pedicle to ensure adequate length for ligation of the pedicle and that the clamp extends far enough beyond the structures within the pedicle to engage the suture. A second clamp is placed above and adjacent to the first under direct vision. A third clamp is placed on the pedicle near the renal parenchyma. The pedicle is divided between the second and the third clamps, leaving vascular stumps protruding. A 0 silk suture is looped below the lower clamp to tie off. It is prudent to tie the pedicle twice and also use suture ligature to minimize the risk with silk ties, which may slip off the vascular pedicle. Various other techniques can be utilized for controlling the vascular pedicles (Figs. 60-30 and 60-31).

In the emergent condition of loss of control of the renal hilar vascular pedicle, it is important to stay calm. The surgeon must inform the anesthesiologist and all operating room personnel of major bleeding and request aggressive hydration and availability of blood products. Compression can be applied using a fingertip or sponge stick to achieve hemostasis as best as possible so that the rest of the operating room staff can prepare. Compression can also be applied on the IVC and/or aorta to control bleeding. Two Yankauer suction tubes can be used to clear the surgical wound. Vascular occlusion clamps are used to clamp and ligate actively bleeding vessels. Clamping should not be done blindly; rather, one should suction, pack, retract, and dissect to get better exposure. If the bleeding is occurring from the renal artery, the surgeon can compress the aorta above the renal artery, clamp the arterial stump with a vascular clamp, and repair the defect with two layered running vascular sutures. If the bleeding is occurring from the IVC because of an avulsed or lacerated renal vein, or avulsed gonadal or

Figure 60-30. A to C, "Cut first, ligate second" method for securing the renal hilum. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-29. Whole-pedicle clamp method for securing the renal hilum. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-31. A and B, “Ligate first, cut second” method for securing the renal hilum. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman’s atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

lumbar vein, a finger can be placed on the hole until the hole can be grasped with an Allis clamp (Scanlan International, St. Paul, MN). Pulling up on the clamp will normally stop the bleeding, allowing the defect to be visualized for repair.

For repair, polypropylene (Prolene) sutures (Ethicon, Cincinnati, OH)—typically 30 inch or 36 inch (75 cm or 90 cm)—are used; 3-0 or 4-0 sutures can be used for IVC or aortic repairs and 4-0 or 5-0 sutures can be used for renal vessel repairs. We recommend using double-armed sutures with tapered needles— $\frac{3}{8}$ circle BB (17 mm) for arterial repair (they are less likely to fracture a calcific arterial plaque) and $\frac{1}{2}$ circle RB-1 (17 mm) or SH (26 mm) for venous repair.

Regional Lymphadenectomy for Renal Cancer

The role of regional lymphadenectomy for renal cell carcinoma (RCC) has remained controversial. Multiple retrospective studies have suggested a possible benefit to regional lymphadenectomy for carefully selected patients (Blute et al, 2004a; Kim et al, 2004; Lam et al, 2004, 2006; Crispen et al, 2011; Capitanio et al, 2013; Sun et al, 2014). A prospective randomized trial that was carried out by the European Organization for Research and Treatment of Cancer included 772 patients. Patients were randomly assigned to two groups—one that underwent regional lymphadenectomy and one that did not. While no overall survival benefit was shown for patients who underwent regional lymphadenectomy for management of RCC, the study included a high percentage of patients with localized small and low-stage tumors who may not have benefited from lymphadenectomy at all (Blom et al, 2009).

For right-sided renal masses when lymphadenectomy is considered, the paracaval, precaval, retrocaval, and interaortocaval nodes from the right crus of the diaphragm to the bifurcation of the IVC are sampled (Fig. 60-32). A right-angle clamp and electrocautery are used to split the lymphatic tissue from the anterior surface of the IVC. The lymphatic tissue is cleared cranially from the right crus of the diaphragm (located 3 to 4 cm above the right renal vein) and caudally until the bifurcation of the IVC. The right gonadal vein is ligated at its insertion into the IVC with 2-0 silk suture, in order to avoid avulsion of the vein. Next the lymphatic tissue is cleared off the lateral aspect of the IVC (paracaval nodes). The IVC is gently

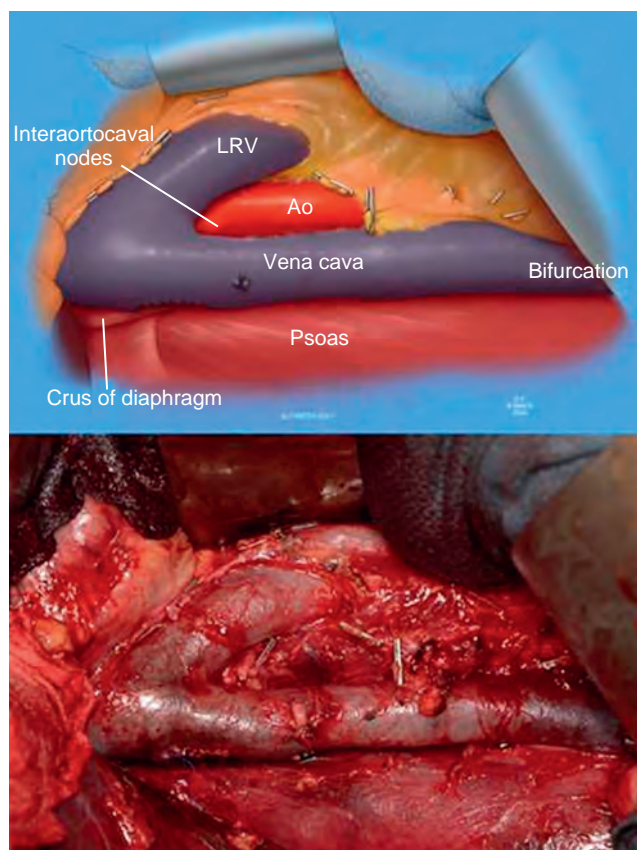

Figure 60-32. Extended lymphadenectomy for right-sided renal masses. Ao, aorta; LRV, left renal vein.

elevated with a vein retractor to expose the lumbar branches. The lumbar veins (typically four or five branches on either side of the IVC) are carefully ligated with 3-0 silk ties and transected. The lymphatic trunks located above the renal vein are ligated with surgical clips. Care to adequately ligate the lymphatic trunks is essential since large quantities of lymph and chyle drain through the cisterna chyli and thoracic duct, and failure to appropriately control them can result in chylous ascites (Fig. 60-33 on the Expert Consult website). Once the lumbar veins are secured and the superior aspect of the lymphatic trunk above the renal vein is secured, the assistant rolls the IVC medially with gentle pressure using two sponge sticks. Next the lymphatic tissue is cleared off the retrocaval region. The nodal tissue overlying the anterior surface of the aorta is then split and divided to the superior border of the left renal vein. Division of the nodal packet is followed to the medial border of the IVC and the aortocaval nodal packet is cleared to the level of the common iliac vessels.

For left-sided renal masses, the lymphatic tissue on the antero-medial surface of the aorta is clipped and divided and rolled laterally (Fig. 60-34). The split is continued cranially along the aorta to the level of the superior mesenteric artery (SMA) and caudally past the inferior mesenteric artery (IMA) to the bifurcation of the aorta. While the IMA and the celiac trunk have to be preserved, the IMA can be tied and divided in case of involved lymphadenopathy. Once the lymphatics are dissected off the anterior and lateral surface of the aorta, the assistant gently elevates the aorta on either side to expose, secure, and divide the lumbar arteries. Once the lumbar arteries are properly secured, the aorta is rolled medially and the tissue between the anterior longitudinal vertebral ligament and the aorta (retroaortic lymph nodes) is resected. The interaortocaval nodes are resected only if they are palpable or visualized on preoperative imaging, or if there is extensive nodal involvement around the aorta.

Figure 60-34. Extended lymphadenectomy for left-sided renal masses. IMA, inferior mesenteric artery; LRA, left renal artery.

Wound Closure

Once the surgical procedure is completed, the surgeon should investigate for hemostasis and evaluate adjacent organs for any signs of injury. The diaphragm and pleura are tissues that can be inadvertently injured secondary to retraction during radical open renal surgery. To test for pleural injury, the retroperitoneum is filled to the level of the flank incision with saline. The anesthesiologist then inflates the lungs with high inspiratory volumes. Bubbling of saline irrigation in the retroperitoneum with deep inspiration would suggest a pneumothorax. In case of a small pleural injury, the pleural cavity can be closed with running nonabsorbable sutures. Prior to complete closure of the pleura, the tip of a 14-Fr red rubber catheter is placed in the pleural cavity. The end of the catheter is placed in a saline-filled bowl. The anesthesiologist provides a deep inspiratory breath to evacuate any air from the pleural cavity through the red rubber catheter and into the saline bowl. Once the air is evacuated from the pleural cavity as evidenced by bubbles in the saline bowl, the red rubber catheter is removed and the assistant cinches the pleural incision tight for an airtight closure. A postoperative chest radiograph is essential to assess for any significant pneumothorax, even in cases when pneumothorax is not suspected.

The fascial layers are approximated typically in two layers—the transversus abdominis and internal oblique fasciae are approximated together, and the external oblique fascia is approximated as a separate layer. A 1:1 mixture of bupivacaine (0.5%) and lidocaine (1%) solutions is injected into the wound for pain control. The subcutaneous tissue is approximated using 3-0 absorbable sutures. The skin is approximated with skin staples or subcuticular 4-0 poliglecaprone 25 (Monocryl) suture (Ethicon, Cincinnati, OH).

Intra- and Postoperative Complications

Damage during Suprahilar and Retrocrural Lymphadenectomy. Dissecting the lymphatic tissue located above the left renal vein (suprahilar and retrocrural nodes) in the interaortocaval space should be undertaken with great caution and care because the duodenum, pancreas, superior mesenteric artery, celiac trunk, superior mesenteric autonomic plexus, and cisterna chyli can all be easily damaged in this area with serious sequelae. In general, we consider dissecting this area if the nodes are noticeably palpable or enlarged on preoperative imaging.

Injury to the Vasculature of the Gut. During radical nephrectomy, a number of important gastrointestinal blood vessels may be encountered that have become involved by tumor, resulting in iatrogenic injury. The inferior mesenteric artery provides the blood supply to the distal transverse, descending, and sigmoid colon. It can be safely ligated as long as the marginal artery of the colon (marginal artery of Drummond, arch of Rioloan) is patent and can supply blood from the SMA to the left colonic arcades. The SMA provides the blood supply to the entire small bowel as well as to the cecum and ascending and transverse colon, whereas the celiac trunk feeds the esophagus, stomach, pancreas, liver, spleen, and part of the duodenum. Ligation of either the SMA or the celiac trunk is a catastrophic event that occurs predominantly with left-sided nephrectomy and that must be rapidly reversed if the patient is to survive. A vascular surgeon should be immediately called to the operating room and the vessel in question should be repaired.

The inferior mesenteric vein (IMV) is found in the mesentery of the descending colon, immediately lateral to the ligament of Treitz. It is a useful landmark for mobilization of the right colon and small bowel mesentery to access the retroperitoneum, because the posterior peritoneum is incised immediately medial to the IMV. The IMV can be safely ligated during surgery without consequence.

In contrast, the superior mesenteric vein (SMV) should not be ligated unless that is the only surgical option. It runs in the root of the small bowel mesentery and joins the splenic vein and IMV to form the portal vein. Repair of an SMV laceration is done by first clipping the small venous branches entering the SMV and then isolating the injury with atraumatic vascular clamps. Venorrhaphy

Figure 60-33. Renal lymphatic drainage and location of the cisterna chyli. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-35. A, Contrast-enhanced computed tomography scan demonstrating right renal mass. B, Three-dimensional reconstruction demonstrates a large intrarenal component to the mass. C, Arterial reconstruction shows lower pole renal artery in close proximity to the renal mass.

using 6-0 Prolene is usually adequate to repair the vein. If the vein has been ligated and transected, serious bowel edema and venous engorgement will result, which can impair venous return through the portal venous system. The net result is the development of systemic hypotension/splanchnic hypertension syndrome, which is characterized by venous thrombosis, bowel ischemia, and necrosis. If possible, a ligated SMV should be reanastomosed primarily or repaired using autologous venous grafting. Gore-Tex vascular grafts (W. L. Gore & Associates, Flagstaff, AZ) should only be used when autologous veins are not available because the thrombosis rate is high. The abdomen should not be closed primarily in cases of SMV injury because abdominal compartment syndrome will occur.

Injury to the Liver and Spleen. Small hepatic injuries (capsular tears and minor lacerations) can usually be managed effectively by argon beam coagulation or electrocautery. Fibrin glue and topical hemostatic meshes (e.g., Surgicel Absorbable Hemostat, Ethicon, Cincinnati, OH) are useful adjuncts. More serious splenic injuries can be managed by splenorrhaphy or splenectomy. Minor hepatic lacerations can be repaired using the same basic principles as for a partial nephrectomy closure, with a synthetic absorbable suture on a $\frac{1}{2}$ circle tapered needle and Nu-Knit pledgets as described later (see [Enucleation for Small Cortical Tumors](#)).

Injury to the Duodenum. Most intramural hematomas of the duodenum should be managed expectantly. However, if the hematoma is large and narrowing the duodenal lumen, incision of the serosa and muscularis (but not the mucosa) can be performed to drain the hematoma and achieve hemostasis. The defect should be closed in one layer with interrupted 3-0 silk sutures. The involved segment may initially appear nonviable; however, no resection should be performed since the initial perception is false. Consultation with a general surgeon or gastrointestinal surgeon can be very helpful.

Minor electrocautery or laceration injuries should be managed by careful debridement of the nonviable tissue and closure in two layers, the mucosal layer with continuous 4-0 chromic or Vicryl suture on a $\frac{1}{2}$ circle tapered needle, and the serosa and muscularis layer with 3-0 silk interrupted suture on a $\frac{1}{2}$ circle tapered needle. An omental flap is placed over the injury and a closed suction drain is inserted.

Injury to the Pancreas. The first step in management of pancreatic injury is a thorough inspection of the organ. Superficial lacerations and contusions can usually be managed by applying fibrin glue and inserting a closed suction drain. The drain is monitored for an alkaline pH and lipase/amylase levels to determine whether a pancreatic fistula is developing. If the injury to the pancreas is deep and/or involves the pancreatic duct, consultation with a

gastrointestinal surgeon is essential for appropriate repair and management.

Pulmonary Complications. Large postoperative pleural effusions can be managed by aspiration initially, followed by chest tube drainage if necessary.

Partial Nephrectomy for Malignant Disease

When technically feasible, partial nephrectomy is the preferred method of choice for managing most renal masses in order to preserve maximum renal function ([Fig. 60-35](#)). While in the past partial nephrectomy was reserved for specific conditions (bilateral tumors, tumor in a solitary kidney, patient at high risk of future renal failure) and small tumors less than 4 cm in diameter ([Novick et al, 1991](#)), indications for partial nephrectomy have considerably widened to include most renal masses that can be safely and completely removed independent of their size ([Blute et al, 2003](#); [Gill et al, 2007](#); [Blute and Inman, 2012](#)).

Relative contraindications to partial nephrectomy include:

Technical issues

- Cold ischemia time greater than 45 minutes (consider extracorporeal approach)
- Less than 20% of global nephron mass retained

Cancer-related issues

- Diffuse encasement of renal pedicle by tumor
- Diffuse invasion of central collecting system
- Tumor thrombus involving major renal veins
- Adjacent organ invasion (stage cT4)
- Regional lymphadenopathy (stage cTxN1)

Preoperative Considerations

In addition to the preoperative considerations for radical nephrectomy, there are additional concepts to consider related to partial nephrectomy.

Hyperfiltration Injury. When a significant portion of renal parenchyma is removed, the renal blood flow is delivered to a smaller number of nephrons, which can lead to increased glomerular capillary perfusion pressure that results in an increased single-nephron glomerular filtration rate called *hyperfiltration* ([Steckler et al, 1990](#); [Goldfarb, 1995](#)). Over decades, the hyperfiltration can injure the remaining nephrons, resulting in focal segmental glomerulosclerosis and the clinical manifestations of proteinuria and progressive renal failure. Hyperfiltration injury is most common when the total nephron mass of both kidneys is reduced by more than 80%.

Figure 60-36. A and B, Partial nephrectomy for a large polar tumor using a Satinsky clamp on the renal parenchyma for ischemia.

Renal Ischemia and Hypothermia. To minimize blood loss and allow for adequate surgical visibility, it is often necessary to employ vascular compression during partial nephrectomy. Options include manual compression, a renal compression clamp (Kaufmann clamp), selective clamping of the renal artery, and en bloc clamping of the entire renal pedicle. Manual and clamp compression of renal parenchyma is preferable, since vascular clamping is associated with a higher incidence of renal complications (Fig. 60-36). It is unclear whether leaving the renal vein unclamped for retrograde renal perfusion offers any tangible benefit. Attempting to limit warm ischemia to 20 minutes and cold ischemia to 35 minutes helps maintain renal function (Thompson et al, 2007).

Adequate renal hypothermia (core renal temperature of 20° C) takes at least 15 minutes to achieve if the kidney is packed with ice slush. To help prevent acute postoperative renal failure, intravenous mannitol (12.5 g) and furosemide (20 mg) should be infused about 15 minutes before renal artery clamping (Hanley and Davidson, 1981; Tiggeler et al, 1985). While evidence supporting this practice is somewhat limited, both drugs are quite safe as long as the patient is well hydrated (Novick et al, 1991).

Enucleation and Surgical Margin. Simple tumor enucleation can be safely conducted in small renal tumors while preserving a small rim of normal tissue and a negative surgical margin (Carini et al, 2006).

Multifocality and Tumor Size. The incidence of multifocality is approximately 2% for clear cell and chromophobe RCC and 10% for papillary RCC (Fig. 60-37). Multifocal tumors are also more common as the primary tumor size increases (Blute et al, 2003). Careful inspection of the entire renal surface should be done at the time of partial nephrectomy to ensure that intraoperative findings corroborate preoperative imaging studies. If additional unanticipated renal mass(es) are encountered intraoperatively, partial nephrectomy is still the treatment of choice for multifocal tumors as long as they can be safely resected with clear surgical margins.

Hereditary Renal Malignancy. Hereditary renal tumors are usually multifocal and bilateral, with high likelihood of recurrence. Except for patients with hereditary leiomyomatosis and RCC who should be aggressively treated with wide excision, most patients with hereditary syndromes can be safely observed with little chance of metastasis until the renal tumors reach 3 cm in size (Maher et al, 1991; Seizinger, 1991; Richards et al, 1993). When partial nephrectomy is performed, the perirenal fat and renal fascia should be preserved. The entire renal surface should be visualized and all visible tumors should be resected. Intraoperative ultrasound can be used to identify any subcortical tumors that could also be resected (Fig. 60-38 on the Expert Consult website). Hypothermia is advisable to minimize injury to the renal parenchyma.

Enucleation for Small Cortical Tumors

The surgeon should ensure that renal cooling is available, even though ischemia time seldom exceeds 30 minutes. Two cylinder-shaped cigarette-like bolsters are prepared by rolling Nu-Knit

Figure 60-37. Three-dimensional computed tomography reconstruction demonstrating a hilar tumor and peripheral tumor.

Absorbable Hemostat (Ethicon, Cincinnati, OH) and tying each end with absorbable sutures. Two pledgets are prepared by folding Nu-Knit into a double-layer strip 5 to 10 cm wide and 1 cm long. We prefer Nu-Knit because it is absorbable and it maintains its integrity without immediate shrinkage when wet. In addition, it has excellent tensile strength when sutured.

The kidney is exposed using either the anterior subcostal or flank approach as described earlier. The entire surface of the kidney is freed of perirenal fat, with the exception of the perirenal fat overlying the tumor. While removing the perirenal fat, special care should be taken to avoid injury to the ureter, particularly for lower pole tumors. Intravenous mannitol and furosemide are administered and the renal pedicle is exposed sufficiently to allow safe application of a vascular clamp if necessary. Vessel loops are placed around the renal vein and artery individually.

The renal cortex surrounding the tumor is marked circumferentially using electrocautery. The plane outside the tumor pseudocapsule and within the normal parenchyma is identified and bluntly dissected with small closed Metzenbaum scissors. For enucleation of small lesions, renal occlusion is usually not necessary. However, if there is excessive bleeding that hampers proper visualization of the resection margin, then manual compression of the kidney or clamping of the renal pedicle can help. When small vessels within the kidney are encountered they are divided sharply with scissors. The tumor is excised and the margins are examined for gross evidence of a positive surgical margin; the deep margin of the excised tumor is assessed by frozen-section analysis. Small bleeding vessels

Figure 60-38. A and B, When performing intraoperative ultrasound for assessment of the renal tumor, the probe is passed over the kidney in radial angles to the center of the tumor. This allows assessment of the subcortical extent of the tumor in each angle, by assessing the transition from normal kidney to tumor interface in multiple planes. On the basis of this assessment, the position and line of incision are selected. (From Graham SD Jr, Keane TE, editors. Glenn's urologic surgery. 7th ed. Philadelphia: Lippincott Williams and Wilkins; 2010.)

in the renal parenchyma are controlled with 4-0 absorbable figure-of-eight sutures on a tapered needle or by coagulation with an argon beam coagulator or bipolar electrocautery. The integrity of the collecting system is verified by checking for injury and repairing with absorbable suture if necessary (Fig. 60-39).

A Nu-Knit pledget that was prepared earlier is placed along each border of the excised renal parenchyma and in the bottom of the

excised parenchyma (Fig. 60-40). The defect is closed with 2-0 absorbable horizontal mattress sutures on a long tapered $\frac{1}{2}$ circle needle. The suture is placed through the pledget and about 1 to 2 cm into the renal parenchyma to prevent capsular and parenchymal tearing. The pledgets allow even distribution of tension along the renal capsule, reducing the likelihood of tearing the capsule. If clamping was used, the pedicle is unclamped and inspection is

Collecting system involved

Figure 60-40. A and B, A Nu-Knit pledget is placed along each border of the crater and a Nu-Knit bolster is placed into the bottom of the crater (not required if the defect is very small). The defect is closed with a 2-0 absorbable horizontal mattress suture. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

done for bleeding, ischemia, or urine leakage of the kidney and for adjacent organ trauma.

The perirenal fat and renal fascia are replaced around the kidney. A closed suction drain in the pararenal space is placed to monitor for bleeding and urine leaks. The closed suction drain is removed after 2 to 5 days when the output is minimal. A Foley catheter is used to monitor the urine output. Unless there is a large renal collecting system defect, a ureteral stent is not typically required.

Wedge Resection for Large Cortical Tumors

For large tumors, intravenous mannitol and furosemide are administered, then the renal artery is clamped with a vascular bulldog clamp. Based on the surgeon's preference, when partial nephrectomy is being performed for larger tumor sizes or lesions that are close to the renal hilum, the renal vein may also be clamped after clamping the renal artery to provide better hemostasis during partial nephrectomy (Fig. 60-41). A plastic bag or sheet is placed around the kidney and filled with ice slush. The kidney is allowed to cool to 20° C (approximately 15 minutes).

The renal capsule is circumferentially incised 5 to 10 mm peripheral to the tumor with electrocautery. Using a combination of blunt and sharp dissection with Metzenbaum scissors, the tumor is

excised with a small rim of normal parenchyma. The specimen is inspected for visible tumor at the resection margin, then submitted for frozen-section analysis.

Bleeding vessels are controlled with figure-of-eight sutures or with argon beam or bipolar electrocautery. The deep resection margin of the kidney must be inspected for any residual tumor or any sign of collecting system injury. If there is any doubt about collecting system injury, 10 to 20 mL of diluted indigo carmine is injected into the renal pelvis while occluding the ureter to assess for leaks. The collecting system is closed with 4-0 absorbable suture on a tapered needle.

The renal parenchymal defect is reconstructed using Nu-Knit bolsters and pledgets as described above. Fibrin glue is applied to the renal parenchymal defect. Finally, the renal vessels are unclamped—if the renal vein as well as the renal artery is clamped, the renal vein is unclamped first followed by unclamping the renal artery.

Segmental Nephrectomy for Large Polar Tumors

Intravenous mannitol and furosemide are administered and the renal pedicle is completely dissected, including the segmental branches (Fig. 60-42; Fig. 60-43 on the Expert Consult website).

Figure 60-41. A, The renal capsule is circumferentially incised 5 to 10 mm peripheral to the tumor with electrocautery. B, A combination of blunt and sharp dissection with Metzenbaum scissors is used to excise the tumor with a small rim of normal parenchyma. C, Bleeding vessels are controlled and the collecting system is closed. D, The defect is reconstructed using Nu-Knit bolsters and pledgets. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-43. Injury to the posterior segmental artery must be avoided.

A bulldog clamp is applied to the apical segmental artery (or basilar segmental artery for lower pole tumors) and the line of ischemia is observed. The avascular line can be further demarcated by injecting 5 mL of indigo carmine directly into the clamped artery (Fig. 60-44 on the Expert Consult website). The line of ischemia is the optimal site for transection of the kidney and should be lightly marked with electrocautery. The apical segmental artery is ligated, then the renal pedicle is clamped en bloc with a curved Satinsky clamp. A plastic bag or sheet is placed around the kidney and filled with ice slush to cool the kidney to 20° C (approximately 15 minutes). The renal capsule is incised along the line of ischemia with electrocautery. Using blunt dissection, the pole of the kidney is excised (Fig. 60-45). Bleeding vessels are controlled, working expeditiously and accurately. The clamp is released to check for uncontrolled bleeders. If

hemostasis is adequate, collecting system repair is begun; otherwise the pedicle is reclamped and vascular control resumed.

The collecting system is inspected for injury. If the defect in the collecting system is large, a guidewire is inserted into the defect and manually guided into the ureter and bladder. A 6-Fr double-J ureteral stent is inserted over the guidewire with the proximal coil in the renal pelvis. The collecting system is closed with a running 4-0 absorbable noncutting suture.

The renal capsule is closed using Nu-Knit pledgets and horizontal mattress sutures as described earlier. Because the defect is large, we use a larger needle (e.g., XLH, GS-27) for segmental polar nephrectomies and heminephrectomies than for enucleation and wedge resections. Nephropexy should be considered if the kidney is quite mobile; however, injury to retroperitoneal nerves overlying the psoas and quadratus lumborum muscles must be avoided (Fig. 60-46 on the Expert Consult website). The kidney is covered with perirenal fat and renal fascia and a closed suction drain is placed to monitor output postoperatively. The indwelling Foley catheter is removed when the patient is mobile and stable. Depending on the output of the closed suction drain, it can be removed 5 to 10 days postoperatively. If a ureteral stent is used, it should not be removed for 4 to 6 weeks postoperatively. After removal of the indwelling Foley catheter, if the output of the closed suction drain is increased, the transurethral indwelling Foley catheter is reinserted to reduce the intrapelvic urine pressure, which should minimize the output from the closed suction drain.

Complications Associated with Partial Nephrectomy

Urinary Fistulae. Partial nephrectomies that involve incision of the collecting system, because of the size and location of the tumor, increase the possibility of urinary leakage. Most urinary fistulae present themselves in about 1 week postoperatively. Therefore, in cases of deep renal resections, it is advisable to keep the closed suction abdominal drain in place for 7 to 10 days. If a urinary fistula is suspected, the diagnosis is confirmed by checking the effluent for creatinine, which will be present at a level manyfold higher than the serum creatinine level. Alternatively, an intravenous ampule of indigo carmine, when injected and collected in the closed suction drain, can also confirm the diagnosis.

If a closed suction drain is not present and a urinary fistula is suspected, a urinary collection in the retroperitoneum can become

Figure 60-46. Nephropexy of the remnant kidney to the retroperitoneum is achieved with several interrupted sutures.

symptomatic. Abdominal imaging is used to confirm the diagnosis. The treatment of urinary fistulae requires three tubes: (1) a retroperitoneal closed suction drain to collect the urinoma, (2) a double-J ureteral stent that is placed after retrograde pyelography, and (3) a Foley catheter to keep the entire collecting system at low pressure. Most fistulas resolve within 4 to 6 weeks with conservative management, and reoperation is rarely required.

Postoperative Bleeding. Delayed bleeding can occur following partial nephrectomy, particularly in patients who require postoperative anticoagulation therapy. If a drain is in place, initial management is conservative and consists of bed rest, hydration, close clinical monitoring, and serial evaluations of blood counts. In situations when more than 1 to 2 units of transfused blood products are required, renal angioembolization should be attempted. Usually, bleeding segmental and subsegmental arteries can be selectively embolized and the kidney salvaged without need for complete nephrectomy. Life-threatening hemorrhage can also occur and require complete angioinfarction of the kidney or reoperative exploration.

Renal Insufficiency. Acute renal failure may follow partial nephrectomy in a solitary kidney, related to large size of the tumor, excessive removal of renal parenchyma, and prolonged ischemic time. Obstruction of the collecting system, drug toxicity, vascular thrombosis, and vascular disruption are other causes that should be considered. While most cases of postoperative renal insufficiency are mild and temporary, some cases require hemodialysis for electrolyte and fluid management. Hyperfiltration injury can also cause a gradual decrease in renal function over time, typically associated with proteinuria.

Vena Caval Thrombectomy

Tumor thrombus within the venous drainage system of the kidney can occur with many retroperitoneal tumors. In children, Wilms tumor, clear cell sarcoma of the kidney, adrenocortical carcinoma, and neuroblastoma can all be associated with IVC thrombi. In adults, urothelial carcinoma of the renal pelvis, lymphoma, retroperitoneal sarcoma, adrenocortical carcinoma, pheochromocytoma, and angiomyolipoma are all potential sources of an IVC thrombus. RCC is the most common cause associated with IVC tumor thrombus, accounting for 18% of all tumors that have venous thrombi (Blute et al, 2004b). The two components associated with IVC thrombi are tumor thrombus (tumor cells contained within bland thrombus) and bland thrombus (blood coagulum without tumor cells). Venous drainage is hampered by venous thrombus encouraging formation of bland thrombus. Distinction between these two forms of venous thrombus is critical and forms the basis of operative management for IVC thrombi.

Management of a tumor with associated IVC thrombus can be technically challenging. In the case of RCC with venous thrombus, 10% have associated positive regional lymph nodes, 25% have associated metastases, and 50% have perirenal fat invasion. Usually, IVC thrombectomy is accompanied by radical nephrectomy and regional lymph node dissection.

Preoperative Considerations

Pulmonary Embolism, Anticoagulation, and IVC Filters. Patients with renal tumors are at increased risk of pulmonary embolism as a result of malignancy-associated hypercoagulability and venous thrombus embolization. We suggest anticoagulation with intravenous or low-molecular-weight heparin to be started as soon as tumor thrombus is detected. Although evidence supporting the use of preoperative anticoagulation is limited, several potential benefits include reduced risk of pulmonary embolism, tumor thrombus shrinkage, and bland thrombus shrinkage and/or prevention. Temporary suprarenal IVC filters are also an option for patients with level 0, I, and II tumor thrombi. However, because of the risk of contralateral renal and hepatic vein thrombosis, the risk of provoking embolization, and the impediment that these devices can pose to future IVC thrombectomy, we do not recommend use of supra-

renal IVC filters. Given the risk of intraoperative thrombus detachment and the possibility of interval thrombus growth in the period immediately preceding surgery, we recommend the use of transesophageal echocardiography (TEE) for level II to IV thrombi.

Preoperative angioembolization can be considered since tumor thrombi have an independent blood supply arising from the renal artery and/or aorta in one third of cases. Angiographic infarction of the blood supply to the tumor thrombus can help shrink a large thrombus to a more manageable size, potentially avoiding the need for bypass or extensive mobilization of the liver. Angioembolization can be considered when caval thrombi appear to invade the IVC, when the thrombus invades the intrahepatic or suprahepatic veins and cannot be excised, when the thrombus is associated with a bleeding kidney, and when deep hypothermic arrest is planned since the patency of the coronary arteries can be simultaneously assessed. The optimal timing for angioembolization is unknown but at most centers, when undertaken, it is usually performed 1 day prior to surgery. There is a potential risk of causing iatrogenic pulmonary embolization of the tumor thrombus when angiography is performed; however, this risk appears to be minimal. We seldom use angioembolization but, if performed, it is associated with ischemia-related flank pain and tumor lysis syndrome.

Urologists who do not routinely handle the IVC and aorta should consult a vascular surgeon for level II and III thrombi to aid in vena caval control and reconstruction. Consultation with a cardiothoracic surgeon preoperatively for all level III and IV thrombi is essential, since access to the mediastinal compartment for vascular bypass and thrombus removal may be required. Involvement of a cardiologist or cardiac anesthesiologist is essential for level II to IV thrombi to allow for intraoperative TEE.

Tumor Thrombus Level. Traditionally, IVC thrombi have been defined and managed according to the cranial extent of the tumor thrombus (Fig. 60-47). MRI provides excellent overall assessment of the level of tumor thrombus involvement; however, reconstructed CT angiograms can also produce excellent images to determine the level of the tumor thrombus. Assessment of the bland thrombus, a grouping system that complements the traditional tumor thrombus levels, can help with intraoperative decision making (Tables 60-1 and 60-2). The key addition of this grouping system is the consideration of the location and extent of bland thrombus and its impact on IVC management (Fig. 60-48).

Level I Vena Caval Thrombectomy: Right-Sided Tumor

Usually, level I thrombi are partially occlusive, are nonadherent, and do not require extensive IVC dissection or any form of bypass. Some groups mobilize the kidney after the thrombectomy is complete, in order to minimize the risk of embolization, while others mobilize the kidney first followed by thrombectomy.

Using an anterior midline, anterior subcostal, or modified flank incision, access is gained to the kidney as previously described. The great vessels and the renal hilum are exposed. Using care not to manipulate the renal vein or IVC too much, the renal artery is identified in the interaortocaval region and secured with 0 silk ligature or a large clip. Ligating the renal artery early will help reduce the blood flow to the kidney and minimize the amount of potential blood loss. The kidney is mobilized outside the renal fascia and the IVC is dissected above the right renal vein. The left renal vein, suprarenal IVC, and infrarenal IVC are identified and secured with vessel loops. To help with temporary ligation of these vessels, 3- to 6-inch portions of an 18-Fr red rubber catheter are passed through the vessel loop and used as Rummel tourniquets (Fig. 60-49 on the Expert Consult website). While this degree of vascular control may not be necessary for all level I thrombi, it is prudent to have adequate vascular control if there is any doubt about the extension of the level of thrombus. Starting cranially, the IVC is gently pinched closed, and then the Rummel tourniquets are applied so that the infrarenal IVC, left renal vein, and suprarenal IVC are closed in that order. The IVC is milked with the left hand toward the ostium of the right renal vein. A C-shaped Satinsky vascular clamp is placed

around the ostium of the right renal vein partially occluding the IVC (Fig. 60-50), ensuring that the thrombus is located within the jaws of the clamp before complete closure. The IVC is palpated for evidence of any other thrombus. Suction and two sponge sticks (to compress the IVC if necessary) are readied and laparotomy sponges are placed around the renal vein to collect any spillage of tumor thrombus after opening of the renal vein. The renal ostium is circumferentially incised using a scalpel or fine-tipped Metzenbaum or Potts scissors. At least half of the width of the IVC must be maintained for proper closure.

The thrombus is extracted by gentle downward traction on the renal vein. A gauze is wrapped around the renal vein stump and secured with a silk ligature to prevent tumor spillage (Fig. 60-51). The medial attachments of the kidney are dissected, ligating the renal artery again before division.

The IVC is inspected for evidence of residual thrombus, irrigating its lumen with heparinized saline (100 units/mL) for improved visualization. The IVC defect is closed with a running closure using a 4-0 Prolene suture on a BB vascular needle (Fig. 60-52). Prior to tying the knot, the anesthesiologist should apply positive airway pressure, pinch the infrarenal IVC closed, and then release the Satinsky clamp. The surgeon should allow 5 to 10 mL of blood to escape from the caval defect to flush out any residual thrombus fragments and debris before pulling the suture tight and tying the closure. A right regional lymphadenectomy is performed, irrigating the wound copiously with sterile water. The surgeon may consider placement of a closed suction catheter to monitor for bleeding.

Level II Vena Caval Thrombectomy: Left-Sided Tumor

Exposure for a tumor thrombus associated with a left-sided tumor is more difficult since the IVC is best accessed from the right retroperitoneum. Both the right and the left colon have to be mobilized to get adequate exposure. The anterior midline and chevron incisions provide the best access for left-sided tumors associated with tumor thrombi in the IVC.

After a subcostal chevron incision is made, the left colon is mobilized and the left anterior pararenal space is developed. The left renal artery is then identified and ligated near its origin close to the aorta. The adrenal, lumbar, and gonadal branches of the left renal vein are ligated and divided. These branches are often dilated and friable and occasionally contain thrombi. The kidney is mobilized outside the renal fascia and the ureter is divided.

The right colon and small bowel are mobilized, a Kocher maneuver is performed, and the right anterior space is developed and the great vessels are exposed. The IVC is carefully dissected to its bifurcation, ligating the right gonadal vein on its anterior surface. Vascular control is obtained sequentially in the following order: (1) the ipsilateral (left) renal artery is ligated, (2) the infrarenal IVC is clamped, (3) the contralateral (right) renal vein is clamped, (4) the suprarenal IVC is clamped, and (5) accessory hepatic veins are ligated to the caudate lobe (this is an optional maneuver to gain 2 to 3 cm of extra infrahepatic IVC exposure) (Fig. 60-53 on the Expert Consult website). Optionally, one can clamp the contralateral renal artery to prevent renal engorgement while the venous

Reprinted with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

outflow is temporarily clamped. This is more of an issue for left-sided tumors since the right kidney does not have significant venous collateralization to shunt blood when the right renal vein is clamped. While obtaining vascular control, one must be very gentle to avoid dislodging the thrombus. The lumbar veins are ligated and divided as required. Prior to clamping, some may use 0.5 mg/kg of intravenous heparin to prevent clamp-related thrombotic complications. Our experience has been that bleeding, not clotting, is the principal problem encountered with vena caval thrombectomy and we do not routinely heparinize our patients.

The renal vein ostium is circumferentially excised and the incision is extended superiorly onto the anterior surface of the IVC using Potts scissors (Fig. 60-54). A Penfield dissector is used to carefully extract the tumor thrombus from the IVC. Lumbar veins can be a source of troublesome bleeding at this stage and should be ligated or sutured as needed. The gross tumor thrombus and kidney are removed en bloc. The IVC is flushed with heparinized saline and the intima inspected for signs of caval invasion. Any suspicious areas should be biopsied or resected. The IVC lumen can be safely narrowed to about 50% of its preoperative size without requiring special measures. The caval defect is closed with a running 4-0 Prolene suture. Prior to tying the knot, the infrarenal clamp is released and 5 to 10 mL of blood is allowed to seep from the

cavotomy to clear the IVC of air and debris. After tying the suture, the contralateral renal clamp is released followed by the suprarenal IVC clamp. Regional lymphadenectomy is performed, consideration is given to leaving a closed suction drain, and the wound is irrigated and the incision closed.

Level III-IV Vena Caval Thrombectomy: Intra-abdominal Approach

Intrahepatic tumor thrombi are very challenging cases to treat. The operating room should be set up for possible cardiopulmonary bypass (CPB), including deep hypothermic arrest. Intraoperative TEE should be available to measure the cranial extent of the thrombus and to monitor the thrombus for fracture and embolization (Fig. 60-55). Cardiac function is evaluated with TEE so that the anesthesiologist can appropriately manage the patient's hemodynamics.

The key decision for level III thrombi is whether to attempt an intra-abdominal thrombus extraction with complete hepatic mobilization or use a combined intrathoracic/intra-abdominal approach with bypass. This decision can only be made intraoperatively, after the renal artery is ligated, the liver is mobilized, and the IVC is

Figure 60-50. Right-sided level I tumor thrombus. A C-shaped Satinsky vascular clamp is placed around the ostium of the right renal vein, partially occluding the inferior vena cava. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-51. Right-sided level I tumor thrombus. Preventing tumor spillage. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

exposed and evaluated. If the IVC can be clamped below the hepatic veins this is preferable, since the venous return from the liver is significant. As a rule of thumb, patients with free-floating partially occlusive thrombi will not tolerate suprahepatic clamping very well and should probably undergo bypass. Contrarily, patients with completely occlusive thrombi will typically have developed extensive collateral venous drainage networks and therefore tolerate clamping much better (Fig. 60-56). Occasionally, a level IV thrombus can be milked into the abdomen through a small diaphragmatic incision and treated intra-abdominally. It is crucial that IVC control not compromise the operation since bleeding and hypotension can lead to an incomplete tumor resection, a result that is universally fatal. Techniques of bypass are discussed in a later section.

We prefer the anterior midline incision for level III and IV thrombi; however, a chevron incision with added sternotomy can also be used. The right kidney and great vessels are exposed as described for a level I thrombus and the right renal artery is ligated in the interaortocaval area. The infrahepatic IVC is gently dissected. The infrahepatic IVC and left renal vein are isolated and Rummel tourniquets are placed around them.

The liver is mobilized by ligating and dividing the ligamentum teres, the remnant of the obliterated left umbilical vein that is located at the lower free border of the falciform ligament. The falciform ligament is divided with electrocautery up to the upper border of the liver where it branches into the coronary ligament on the right and the left triangular ligament on the left (see Fig. 60-12). The superior layer of the coronary ligament is divided with scissors or electrocautery, taking care not to injure the liver or the IVC, which is located just behind the ligament in the bare area of the liver. Division of the superior layer of the coronary ligament continues along the right border of the liver until it forms the right triangular ligament (the fused superior and inferior layers of the coronary ligament), which should also be divided. Mobilization of the right lobe of the liver is completed by dividing the inferior layer of the

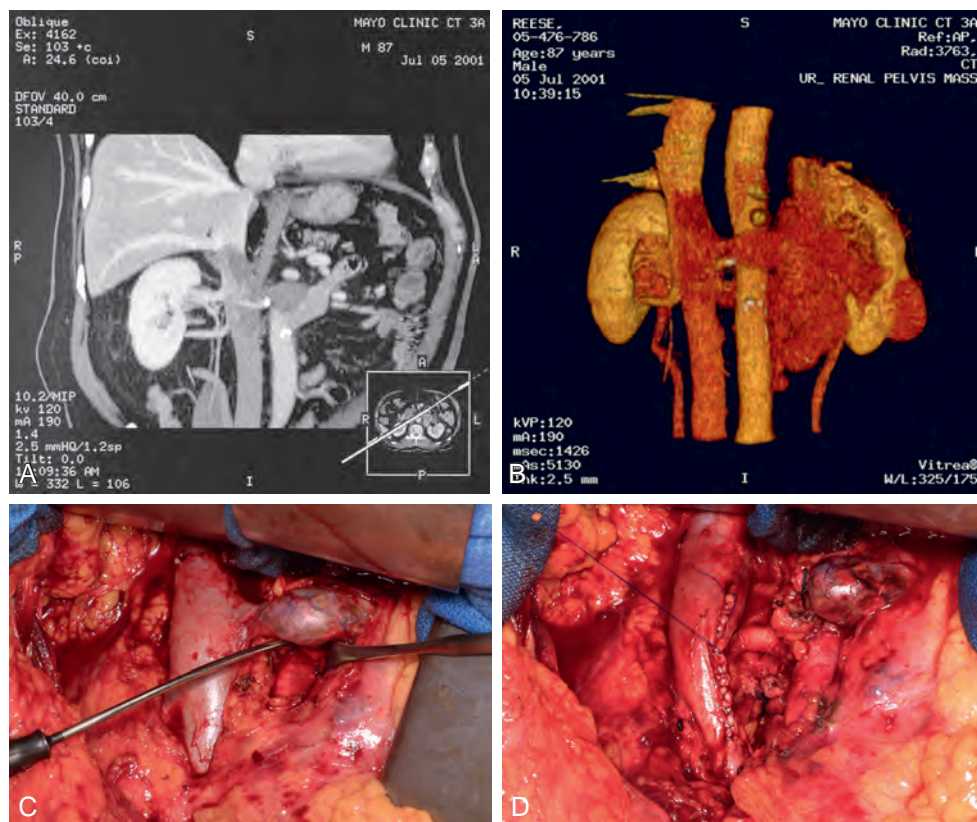

Figure 60-54. Coronal computed tomography scan (A) and three-dimensional reconstruction (B) of a level II left-sided tumor thrombus. C, Securing vascular control. D, Repair of inferior vena cava defect.

coronary ligament, the attachment that ties the liver to the diaphragm, upward toward the IVC.

The left triangular ligament is divided anteriorly and hepatic mobilization is completed by dividing the posterior aspects of the left triangular ligament toward the IVC. The right lobe of the liver can now be safely and gently rotated toward the midline so that the IVC can be evaluated on the posterior surface of the liver (Fig. 60-57). For tumors of the left kidney, it may be necessary to divide the diaphragmatic attachments of the spleen so that it can be rotated toward the midline with the pancreas without being traumatized.

The plane between the posterior surface of the liver and the anterior surface of the IVC is developed. The help of a hepatic surgeon with this portion of the procedure should be considered. This plane contains venous branches from the liver that are divided into upper and lower groups. The most important group is the upper group that contains the right, middle, and left hepatic veins, the principal outflow from the liver, and therefore cannot be divided. Tumor thrombus can extend into these veins and they must be carefully inspected and cleared of any thrombus during thrombectomy. Obstruction of these three veins leads to the Budd-Chiari syndrome. The lower group of hepatic veins (the accessory hepatic veins) drain blood principally from the caudate lobe (with a small contribution from the right lobe) and can be safely divided. The accessory hepatic veins are ligated with 2-0 silk and the plane

between the IVC and the liver is developed. Additionally, the lumbar veins are ligated with 2-0 silk and the plane between the IVC and the posterior abdominal wall is developed. The IVC should now be fully mobilized.

A window is created in the lesser omentum and the porta hepatis (also called the portal triad or hepatic pedicle), which contains the portal vein, common hepatic artery, and common bile duct, is encircled with a Rummel tourniquet. Clamping the porta hepatis (the Pringle maneuver) is necessary to prevent massive blood loss if the IVC is clamped above the major hepatic veins (Fig. 60-58 on the Expert Consult website). Clamping the IVC above and below the hepatic veins while performing a Pringle maneuver is called total hepatic vascular occlusion. If the IVC is clamped below the major hepatic veins and the accessory hepatic veins are ligated, the Pringle maneuver may not be necessary. Under normothermic conditions, the porta hepatis can be clamped for up to 60 minutes, although a clamping time of 20 minutes or less is preferred since ischemic hepatic injury and portal vein thrombosis can ensue. Another complication of the Pringle maneuver is splenic engorgement and rupture as a result of backup of venous drainage from the splenic vein, which normally empties into the portal vein.

The resectability of the tumor and thrombus is determined using TEE and a thorough intraoperative assessment of the anatomy. If the thrombus is below the hepatic veins or can be milked below these veins, it is usually safe to proceed without bypass. If the

Figure 60-57. A and B, Mobilizing the liver to expose the inferior vena cava for management of tumor thrombus. (From Ciancio G, Livingstone AS, Soloway M. Surgical management of renal cell carcinoma with tumor thrombus in the renal and inferior vena cava: the University of Miami experience in using liver transplantation techniques. *Eur Urol* 2007;51:988–95.)

Figure 60-59. A, Coronal magnetic resonance (MR) image demonstrates tumor extending to the level of the diaphragm. B, Sagittal MR reconstruction demonstrates thrombus that extends farther into the right atrium. The patient would eventually require cardiopulmonary bypass and deep hypothermic circulatory arrest.

thrombus involves the hepatic veins or extends above the liver, bypass is often required (Fig. 60-59). The IVC is occluded above the liver and thrombus and the patient's hemodynamic response is observed over 2 to 5 minutes. Clamping the suprahepatic IVC results in a 60% reduction in cardiac preload, an increase in peripheral vascular resistance of 80%, an increase in heart rate of 50%, a drop in cardiac output of 40%, and a drop in mean arterial blood pressure of 10% to 20%. If the cardiac output drops more than 50% or the mean arterial blood pressure drops more than 30%, the patient will not tolerate suprahepatic IVC clamping. Options for managing this situation include bypass (our preference) and clamping of the supraceliac aorta. If the IVC clamping trial is tolerated and the thrombus can be removed in less than 30 minutes, it is safe to proceed with the intra-abdominal procedure.

In sequence, the infrarenal IVC, the contralateral (left) renal vein, the porta hepatis, and the suprahepatic IVC are clamped. For left-sided tumors, the right renal artery should be clamped prior to the right renal vein since there is no good collateral venous drainage

for the right kidney. The ostium of the right renal vein is circumferentially incised and the incision is extended upward toward the intrahepatic IVC. The incision should be large enough to permit extraction of all of the tumor thrombus and careful inspection of the intima of the IVC. The thrombus and kidney are excised (Fig. 60-60). With the help of a Penfield dissector the IVC is cleared of adherent thrombus. A Fogarty balloon catheter (Edwards Lifesciences Corporation, Irvine, CA) or 20-Fr Foley catheter can be used as an embolectomy catheter if the thrombus is out of reach. If involved with tumor that cannot be scraped away, the IVC should be completely or partially resected and reconstructed (see [Patching, Replacing, and Interrupting the Inferior Vena Cava](#)). During deep hypothermic arrest a cystoscope can be used to inspect the hepatic veins and suprahepatic IVC, which allows for a smaller caval incision. The IVC is closed as described for level II thrombus. The hepatic ligaments are tacked back into place to prevent torsion of the liver. A regional lymphadenectomy is performed and a closed suction drain is inserted.

Level III-IV Vena Caval Thrombectomy: Combined Intra-abdominal and Intrathoracic Approach

Level III thrombi that cannot be removed intra-abdominally and most level IV thrombi are managed with a combined intra-abdominal and intrathoracic approach. Thoracoabdominal, chevron laparotomy with sternotomy, and anterior midline laparotomy with sternotomy incisions can be used to provide access to the chest and abdomen (Fig. 60-61 on the Expert Consult website). Our preference is for the anterior midline laparotomy with sternotomy. A cardiothoracic surgeon needs to participate with the planned operation.

The abdominal portion of the case is identical to the intra-abdominal approach described above. Once the abdominal phase

is completed, the cardiothoracic surgeon is called to the operating room and a median sternotomy is performed. The pericardium is opened and the right heart exposed. Often, mobilization of the liver and IVC is easier once the sternotomy is completed (Fig. 60-62).

The blood supply is bypassed using one of the techniques described below. Once on bypass, the ostium of the renal vein is circumferentially excised, the incision is extended cranially on the IVC, and the thrombus is extracted. A right atriotomy is usually performed to help remove the suprahepatic thrombus. The atrium and IVC are then closed. The patient is taken off bypass and thoracotomy tubes and closed suction abdominal drains are placed. The hepatic ligaments are tacked back into place to prevent torsion of the liver and regional lymphadenectomy is performed.

Bypass Techniques for Inferior Vena Cava Surgery

The requirement of bypass significantly complicates and prolongs IVC thrombectomy. However, bypass is often critical to performing the procedure safely and completely and should be used whenever required. Bypass should be considered in patients in whom the IVC cross-clamping trial causes significant hypotension, as well as in patients in whom there is preoperative cardiac or hepatic dysfunction, contralateral renal dysfunction, or portal venous hypertension, and when there is major intraoperative bleeding that is difficult to control.

Venovenous Bypass. This is the least invasive bypass technique for IVC thrombi and involves shunting the venous blood from below the renal veins to the venous return of the heart with the aid of a pump. Venovenous bypass (VVB) can be done without opening the chest, which is a key advantage that it has over traditional CPB. Two main options are available for infrarenal cannulation: a percutaneous approach through the femoral vein or a direct intraoperative approach through the IVC just above its bifurcation. When cannulating the IVC, it is important to position the tip of the cannula as far from the tumor thrombus as possible to avoid dislodging it, which can cause a massive pulmonary embolism, and to

Figure 60-60. Resected renal mass and intact inferior vena cava thrombus.

Figure 60-62. Median sternotomy with pericardium opened exposing the right heart. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

Figure 60-61. Surgical incisions for combined intra-abdominal and intrathoracic approach to vena caval tumor thrombi. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

avoid aspirating and recirculating tumor cells. Several options are available for delivering the shunted blood back to the heart: a percutaneous approach via the internal jugular vein, a cutdown approach to the brachial/axillary vein, and a direct intraoperative approach through the right atrium. One advantage of VVB is that full heparinization is not required, which may help minimize post-operative bleeding problems. However, a key disadvantage is that the blood flow to the intercostal and lumbar arteries and the intercostal and lumbar veins is not interrupted during VVB, a problem that can lead to major bleeding once the cavotomy is performed to extract the thrombus. VVB should not be used when atrial thrombi cannot be completely milked into the IVC, when there is extensive bland thrombus in the iliac veins or infrarenal IVC, or when there is preexisting Budd-Chiari syndrome.

For percutaneous VVB, immediately following intubation, the anesthesiologist should insert an 8- to 18-Fr heparin-bonded arterial cannula into the internal jugular vein using the Seldinger technique (Fig. 60-63). A 6-cm, 18-gauge hollow needle is inserted into the femoral vein, a guidewire is placed, the tract is dilated, and a 14- to 20-Fr heparin-bonded arterial cannula is advanced into the common iliac vein. Both cannulae are connected to a perfusion pump using heparin-bonded tubing. The portal vein can also be cannulated with a 20-Fr cannula and its venous flow returned to the pump, though this is usually not necessary. The incision is performed and the kidney and IVC are dissected. Once all the vessels are clamped, the perfusion pump is started and the thrombectomy is performed under pump, ligating any troublesome lumbar and intercostal veins. Once thrombectomy and IVC repair are complete, the vessels are unclamped in the same order they were clamped.

For open VVB, the kidney and IVC are dissected, the liver is mobilized, and a sternotomy is performed (Fig. 60-64 on the Expert Consult website). A 20-Fr cannula is inserted into the infrarenal IVC well away from the tumor thrombus and then a 14- to 20-Fr cannula is inserted into the auricle of the right atrium. The infrarenal IVC, renal vein, porta hepatis, and suparenal IVC are clamped,

Figure 60-65. Traditional median sternotomy approach with cannulation of the aortic arch, superior vena cava, and right femoral vein for cardiopulmonary bypass. Ao, aorta. (© The Lahey Clinic.)

and then bypass is started. Thrombectomy is performed as quickly as possible.

Cardiopulmonary Bypass with and without Deep Hypothermic Arrest. CPB can be performed with or without deep hypothermic arrest (Fig. 60-65). CPB with hypothermic arrest involves stopping the heart and starting bypass, cooling the patient to 16° C to 18° C, and draining all of the blood from the patient. Although very invasive, CPB with hypothermic arrest offers several benefits. First, it can be used in cases in which the thrombus cannot be milked below an intrapericardial IVC clamp. Second, there is no need to clamp the aorta or porta hepatis or to ligate as many lumbar and hepatic veins since blood flow to these structures is no longer present. However, all vessels that have been traumatized or transected must be controlled since they will bleed once the patient is taken off bypass. Third, the absence of active blood flow allows for complete inspection of the IVC and hepatic veins, thereby aiding in achieving a complete thrombectomy. Fourth, the risk of embolization during thrombectomy is lower. Fifth, the surgeon is allowed up to 60 minutes to perform thrombectomy (although <40 minutes is certainly a better target), whereas IVC clamping without bypass is only tolerated for about 30 minutes.

For CPB with deep hypothermia, the kidney and IVC are dissected and the liver is mobilized. The cardiothoracic surgeon performs the sternotomy, opens the pericardium, and exposes the heart and its vessels. Heparin-bonded cannulae are placed in the infrarenal IVC and the right atrium to collect venous blood and a cannula is placed into the aortic arch for outflow. The patient is heparinized and bypass is started. The aorta is clamped and cardioplegia solution is administered. The temperature of the recirculated blood is dropped to 10° C to 14° C and the patient is cooled for 15 to 30 minutes until a core temperature of 16° C to 18° C is reached. Intraoperative electroencephalography should be performed to determine when the brain has been adequately cooled. When sufficient cooling has been achieved, the perfusion pump is stopped and 95% of the patient's blood volume is drained into the pump reservoir. Tumor thrombectomy should be performed as fast as

Figure 60-64. Technique of open venovenous bypass for removal of supradiaphragmatic vena caval tumor thrombus.

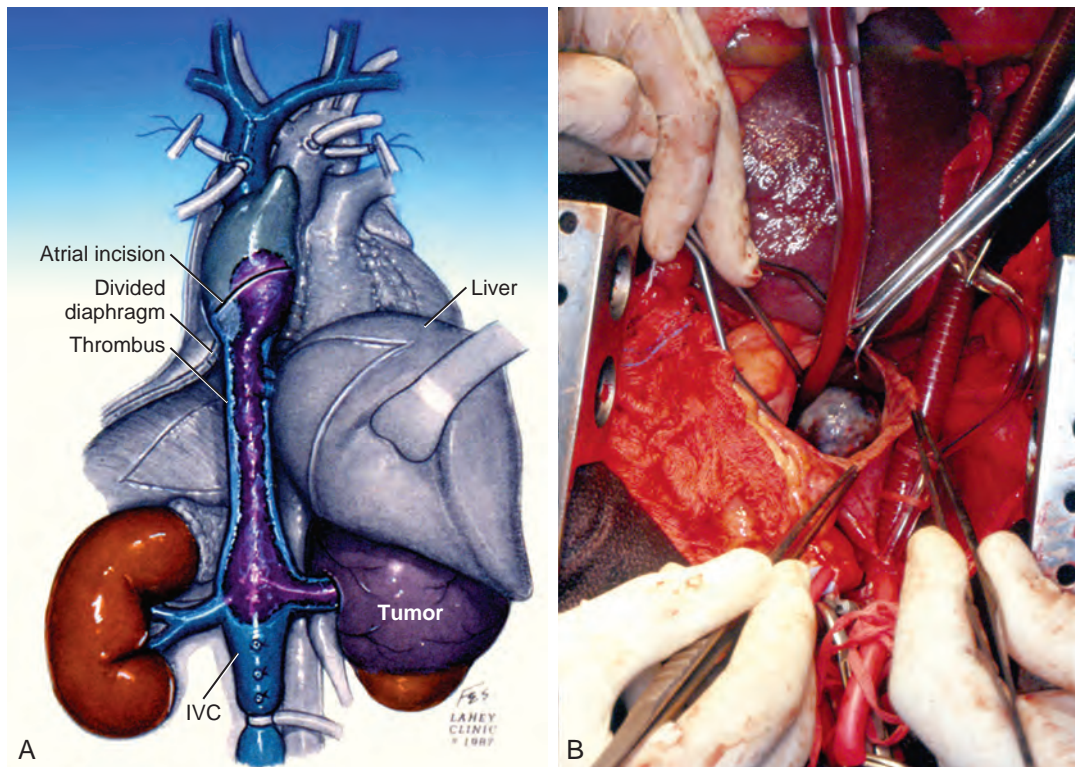

Figure 60-66. A and B, Tumor thrombus extension into right atrium removed using traditional median sternotomy approach and an atriotomy for retrieval of thrombus. IVC, inferior vena cava. (A, © The Lahey Clinic; B, from Wotkowicz C, Libertino JA, Sorcini A, et al. Management of renal cell carcinoma with vena cava and atrial thrombus: minimal access vs. median sternotomy with circulatory arrest. *BJU Int* 2006;98:289–97.)

possible, taking great care to ligate all potential bleeders (Fig. 60-66; Fig. 60-67 on the Expert Consult website). If the patient has known coronary artery disease, coronary artery bypass can be performed at the same time. If the resection is taking longer than anticipated, the surgeon should consider allowing a 10-mL/kg/min trickle of blood to flow to the organs or using retrograde cerebral perfusion.

Once the IVC and right atrium are repaired, warm blood is reinfused from the pump reservoir and CPB is restarted. Hemostasis is performed while the patient warms to 37°C over the next 30 to 45 minutes. Once the heart has restarted pumping, bypass is stopped, the cannulae are removed, and protamine sulfate is administered. Coagulopathy is common and fresh frozen plasma, platelets, and packed red blood cells should be available to administer. Thoracostomy tubes and closed suction abdominal drains are inserted.

Patching, Replacing, and Interrupting the Inferior Vena Cava

Patch Cavoplasty. If the IVC is expected to be less than 50% of its original size, a patch cavoplasty is necessary to prevent IVC stenosis and thrombosis-related events (Fig. 60-68). Autologous and bovine pericardium, polytetrafluoroethylene (PTFE), collagen-impregnated Dacron (DuPont, Wilmington, DE), and autologous saphenous vein are materials that can be used for patch cavoplasty.

The patch is sized to a bit larger dimension than the caval defect, typically configured to an oval shape. A double-armed 5-0 Prolene suture on a BB needle is used to sew the patch in place. Small and regular suture bites will assure a tight closure. Intraluminal inversion of the edges of the patch should be avoided to prevent excess thrombogenesis. Some surgeons prefer tacking both apices of the defect first and then running a strand of suture from each apex to the midpoint between the apices, which requires four knots. Alternatively, the graft can be parachuted into position and sewn into place circumferentially, requiring only one knot. Minimal

Figure 60-68. Vena cava reconstruction using a pericardial patch graft.

Figure 60-67. A and B, Tumor thrombus finger fracture and removal after formal atriotomy with retraction sutures (inset A). Manual displacement from atrium through diaphragm and removal through anterior cavotomy. (© The Lahey Clinic.)

Figure 60-69. Vena cava replacement with polytetrafluoroethylene graft. (From Bower TC, Nagorney DM, Toomey BJ, et al. Vena cava replacement for malignant disease: is there a role? *Ann Vasc Surg* 1993;7:51-62.)

manipulation of the patch is helpful to prevent inadvertent damage to the patch and caval edge. Liberal use of heparinized saline can help with visualization. Prior to the final closure of the cava, the caudal IVC clamp should be released and 5 to 10 mL of venous blood allowed to escape from the cavotomy, providing for removal of air, debris, and clot prior to unclamping the cranial caval clamp.

Vena Caval Replacement. In situations when a circumferential section of IVC has been removed or if a vena cava defect is too large for simple patching, vena caval replacement is necessary (Fig. 60-69). Typically, we use PTFE grafts to replace the IVC, although others have described spiraled saphenous vein, superficial femoral vein, and tubularized pericardium as options (Helfand et al, 2011; Hyams et al, 2011; Quinones-Baldrich et al, 2012; Pulitano et al, 2013). Typically a graft size of 16 to 20 mm in diameter is required. The large diameter of the graft reduces the risk of thrombosis.

The liver is mobilized and the IVC exposed completely. Vascular bypass is used if clinically indicated, and 5000 units of intravenous heparin is administered. The IVC is clamped and the affected portion is excised. The cranial IVC-patch anastomosis is completed first. Subsequently, the graft is clamped followed by releasing the cranial IVC clamp to test the upper IVC-patch anastomosis. Next the graft is sized and cut to fit the IVC defect and the caudal IVC-patch anastomosis is completed. Prior to closure of the lower IVC anastomosis, the graft is unclamped and 5 to 10 mL of blood is allowed to escape from the graft through the cavotomy. The graft is then reclamped and the infrarenal IVC is unclamped, and 5 to 10 mL of blood is allowed to escape from the infrarenal IVC. Closure of the anastomosis is completed by tying the final knot and the IVC is unclamped. The graft is wrapped with omentum or retroperitoneal fat and then the hepatic ligaments are reapproximated to prevent torsion of the IVC graft.

Postoperatively, low-dose intravenous heparin or a reduced dosage of low-molecular-weight heparin is given. Once the patient's bowel function has recovered, lifelong oral warfarin is used with a target international normalized ratio of 2 to 3.

Inferior Vena Cava Filtration and Permanent Interruption for Bland Thrombus

Occasionally, a patient with an infrarenal bland thrombus requires management at the time of tumor thrombectomy. For bland thrombus that is limited to the pelvic veins, intraoperative placement of an infrarenal vena cava filter is indicated. When the bland thrombus diffusely involves the infrarenal IVC, the optimal management is permanent interruption of the IVC. Necessary intraoperative care is required to preserve the collateral lumbar venous drainage, since these vessels provide a "release valve" for the impaired caval blood flow. When the infrarenal IVC is occluded with bland thrombus that is distinct and separate from the tumor thrombus, the best form of management is usually permanent interruption without resection since attempts at complete removal of diffuse organized bland thrombus are almost always unsuccessful and often result in vascular injury. Options for permanent interruption of the IVC include serrated vena cava clips (e.g., Adams-DeWeese clip, Moretz clip), cross stapling with a vascular GIA stapler (Covidien Ltd., Mansfield, MA), suture plication, and suture ligation. Serrated vena cava clips and vascular staplers offer the advantage of easy application, while serrated vena cava clips allow partial blood flow through the IVC.

When the bland thrombus in the infrarenal IVC is admixed with tumor thrombus that has undergone retrograde growth, segmental resection of the IVC with permanent interruption of the IVC will maximize the chance of cure. Since it is not possible to accurately dissect tumor thrombus from bland thrombus and assure complete resection of tumor, resection of the IVC below the level of the contralateral renal vein ostium is recommended. Resection should be as close to the renal vein ostium as possible to prevent turbulent and thrombogenic flow in the upper stump. In addition, maximal preservation of the lumbar veins in the lower stump is important to ensure good collateral drainage.

Perioperative Complications

Air Embolism. Air embolism to the right heart and pulmonary arteries is a serious and potentially lethal complication associated with caval thrombectomy. Risk of air embolism can be significantly reduced by releasing the caudal IVC clamp first and allowing air and some blood (5 to 10 mL) to escape from the IVC repair site prior to removing the cranial clamp.

Acute Pulmonary Embolism. Tumor and bland thrombus can embolize during and after surgery. Minimizing intraoperative manipulation of the kidney and IVC before vascular control helps reduce the likelihood of acute thrombotic pulmonary embolism. Early preoperative or intraoperative placement of a Greenfield filter (Boston Scientific, Natick, MA) in a patient with pelvic bland thrombus can also help reduce the risk of pulmonary embolism. If respiratory distress is encountered during surgery, strong consideration should be given to prompt thoracotomy, pulmonary arteriotomy, and extraction of the thrombus.

Massive Hemorrhage. Major bleeding can occur during and after the surgery. If uncontrolled major bleeding occurs in a patient who is not on bypass, the surgeon should consider clamping the aorta above the celiac trunk or initiating deep hypothermic CPB. However, CPB can also lead to major coagulopathy, potentially worsening the degree of hemorrhage. Fresh frozen plasma, platelets, and red blood cells should be transfused liberally as indicated. Using a Cell Saver (Haemonetics Corporation, Braintree, MA) is not recommended for oncologic surgery since tumor cells can be disseminated.

Hepatic Dysfunction. Temporary hepatic dysfunction, characterized by elevated transaminases and alkaline phosphatase, is common in patients with levels III and IV thrombi that require suprahepatic IVC clamping and/or bypass. Minimizing clamping of the porta hepatis as much as possible can reduce hepatic ischemia and thereby the degree of postoperative hepatic dysfunction. Liver enzymes typically peak 2 to 3 days postoperatively and slowly resolve thereafter.

Organ Ischemia. Cardiac ischemia is most common in patients undergoing suprahepatic IVC clamping without bypass. Patients

with poor preoperative cardiac function are probably best managed by CPB. Renal and intestinal ischemia can also result during thrombectomy, requiring close postoperative monitoring.

KEY POINTS

- The origin of the right renal artery is posterior to the left renal vein and IVC. During a difficult right radical nephrectomy, the right renal artery may be more accessible posterior and medial to the IVC, near the site of origin from the aorta.
- While the right gonadal and adrenal veins drain into the IVC, the drainage of the left gonadal and left adrenal veins is different as they drain into the left renal vein.
- Simple nephrectomy, removal of the kidney within the Gerota fascia, is used for management of benign renal entities.
- The key elements of radical nephrectomy are early ligation of the renal artery and vein and removal of the kidney outside of the Gerota fascia. When technically feasible, the ipsilateral adrenal gland should be spared.
- For left radical nephrectomy, particularly for upper pole renal masses, identification of the left renal artery from the posterior approach is recommended to avoid inadvertent ligation of the superior mesenteric artery, which is on the anterior surface of the aorta 1 to 2 cm cephalad to the left renal vein.
- Regional lymphadenectomy extending from the crus of the diaphragm to the aortic bifurcation is employed in select cases of advanced local disease and when technically feasible.
- The impact of lymphadenectomy on progression-free and overall survival is controversial.
- In order to maintain the maximum number of functioning nephrons, partial nephrectomy is the treatment of choice for stage T1 renal tumors when technically feasible, even in the absence of identifiable renal insufficiency.
- The goal of partial nephrectomy is complete excision of the tumor with negative surgical margins and maximal preservation of benign adjacent parenchyma. Various techniques have been used, including enucleation, polar segmental nephrectomy, transverse resection, wedge resection, and extracorporeal partial nephrectomy with renal autotransplantation.
- In patients with known IVC tumor thrombus, intraoperative TEE should be utilized after the patient is anesthetized and intubated to appropriately assess the distal extent of the tumor thrombus before initiating the surgical procedure.
- When performing right radical nephrectomy with tumor thrombectomy, the suprarenal IVC can be resected, but only if the left renal vein has been ligated distal to its venous tributaries (i.e., gonadal, lumbar, and adrenal veins).
- Given the lack of venous tributaries on the right side, the suprarenal IVC should not be resected for a left-sided tumor unless one provides alternative venous drainage for the right kidney with autotransplantation or a saphenous vein graft to the splenic, portal, or inferior mesenteric vein.
- Alternatives to CPB may include venovenous bypass and extensive liver mobilization.
- When reconstructing the IVC, the lumen can be safely narrowed by half and closed primarily. To maintain the lumen in larger resections the cava can be reconstructed with a pericardial graft or PTFE.

Complications of Laparoscopic Renal Surgery

Penetrance of Minimally Invasive Renal Surgery among Urologists

Summary

OVERVIEW

Surgical treatment is central to addressing many urologic conditions affecting the kidneys. Decades of experience have demonstrated the efficacy and durability of operative extirpation for malignant processes, as well as operative reconstruction for obstruction. Although effective, traditional open surgical approaches to the kidney are associated with significant postoperative discomfort and convalescence. Laparoscopy, compared with open renal surgery, has been shown to result in less change in muscle volume and a lower rate of flank bulge, paresthesias, and numbness postoperatively (Crouzet et al, 2014). Studies have demonstrated that many patients can have permanent body surface alterations with flank incisions resulting in significantly larger postoperative surface area and volume changes on the operated flank compared with the uninvolved flank. Patients report dissatisfaction with the body changes that occur in up to 60% of flank incisions, with a preference toward minimally invasive techniques (Chatterjee et al, 2004; Kobayashi et al, 2004; Park et al, 2011).

Minimally invasive surgical approaches were born out of the desire to address secondary issues related to surgery, including incisional pain, convalescence, and cosmesis. Initially applied for the treatment of stone disease, advances in video technology and surgical tools have now been used to treat the most complex of renal pathologies, with less morbidity compared with standard operative approaches. Clayman and associates initiated this revolution in renal surgery in 1990 when they introduced the laparoscopic nephrectomy (Clayman et al, 1991). This was performed in an octogenarian with a kidney mass, and although the procedure took over 7 hours, its impact on postoperative recovery was immediately apparent compared with the conventional open approach. Subsequently, this minimally invasive approach has been applied to every aspect of operative renal disease as an alternative to open surgery.

Multiple studies have demonstrated that laparoscopic renal surgery provides recuperative as well as cosmetic advantages in contrast to open surgery (Kerbl et al, 1994a; Dunn et al, 2000; Gill et al, 2007; Tan et al, 2011). With experience, all manner of laparoscopic renal surgeries are now routinely accomplished without

compromise to surgical outcomes. Accordingly, the laparoscopic technique, where available, has evolved into a standard in treating a variety of surgical diseases of the kidney. This chapter will discuss indications, present techniques, review results, and outline potential complications of laparoscopy and robotic-assisted laparoscopy as applied to the kidney.

PATIENT EVALUATION AND PREPARATION

Basic principles of laparoscopic surgery are thoroughly discussed in Chapter 10 of the text. Fundamentals of patient selection and preparation for renal surgery largely parallel those of open surgical options for treatment of the underlying pathology. A pertinent history and physical examination are necessary to identify potential issues that could arise during surgery. **Prior abdominal, retroperitoneal, or renal surgery is not a contraindication to laparoscopic surgery; however, the type and extent of prior abdominal surgery may direct technique, positioning, trocar placement, and selection of a transperitoneal versus extraperitoneal point of access** (Chen et al, 1998; Cadeddu et al, 1999). In addition, the patient's body habitus may influence the type of access obtained and the location and configuration of trocar placement (Fugita et al, 2004; Kapoor et al, 2004; Romero et al, 2008). Surgeon experience and availability of equipment will facilitate or deter from use of the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) in treating renal pathology via a laparoscopic approach. Informed consent is obtained with a detailed discussion of potential complications including the potential for intraoperative conversion to open surgery.

Coagulopathies should be corrected to minimize chances of perioperative bleeding. With the increased use of cardiac stenting, more patients are maintained on chronic antiplatelet therapy. These cases warrant discussion with the patient's cardiologist to delineate risks and benefits of continuing or temporarily holding antiplatelet therapy. The decision should be individualized, taking into account the intended renal surgery, type of vascular stent used, and interval since placement in order to minimize the risks of bleeding and

perioperative coronary artery thrombosis. If necessary, complex laparoscopic renal procedures can be performed safely while patients continue antiplatelet therapy (Kefer et al, 2008).

Uremic patients with prolonged bleeding time may benefit from desmopressin acetate (1-desamino-8-D-arginine vasopressin [DDAVP] 0.3 to 0.4 µg/kg) given intravenously an hour before surgery to improve platelet function (Mannucci et al, 1983). However, one must consider a potential side effect of DDAVP therapy, iatrogenic hyponatremia, which is well recognized and has been reported in patients undergoing laparoscopic renal surgery (Humphries et al, 1993; Pruthi et al, 2002).

Laboratory and imaging studies are obtained as indicated by each individual patient's medical history and physical examination. Patients should have blood typed and screened. Crossmatching of blood is at the discretion of each surgeon based on operative experience and expected complexity of the intended procedure. Evidence suggests that mechanical or antibiotic preoperative bowel preparation does not improve outcomes. Hence, the use of bowel preparation is left to the discretion and practice patterns of the surgeon (Sugihara et al, 2013).

Imaging studies that define the pathology should be present in the operative suite to define anatomy and, in conjunction with preoperative site marking, minimize the risk of wrong-side surgery. Angiography, embolization, and stent placement are not routine for laparoscopic renal surgery but may be undertaken in preparation for specific pathologies or procedures.

Anesthetic Considerations for Laparoscopy

Most laparoscopic renal procedures require a general anesthetic, and a patient's pulmonary and cardiac function must tolerate this anesthetic approach (Monk and Weldon, 1992). The pneumoperitoneum can affect patients with severe cardiopulmonary disease by compromising ventilation and venous return (Arthure, 1970; Hodgson et al, 1970; Nunn, 1987; Lew et al, 1992). Patients with chronic pulmonary disease may not be able to compensate for the pneumoperitoneum-induced hypercarbia and may require working at lower pressures, use of helium as an insufflant, specialized laparoscopic trocars minimizing carbon dioxide reabsorption, or open conversion (Monk and Weldon, 1992; Wolf et al, 1996; Makarov et al, 2007; Herati et al, 2009, 2011).

Considerations in Obese Patients

Obesity is not a contraindication to laparoscopic surgery but can make retraction and identification of anatomic structures more challenging. It is for these reasons that laparoscopy in obese patients is associated with an increased risk of open conversion when compared with nonobese patients (Fazeli-Matin et al, 1999). In addition, although complication rates for laparoscopy in obese patients are higher when compared with laparoscopy in the general population (Mendoza et al, 1996; Aboumarzouk et al, 2012), pulmonary and wound complications are lower with laparoscopy when compared with an open approach (Kapoor et al, 2004; Montgomery et al, 2005). Other factors to account for in the obese population include the increased distance to the operative field, which calls for modifying trocar location and number, as well as the use of longer instrumentation (Doublet and Belair, 2000; Jacobs et al, 2000). Consideration must also be given to the weight of the pannus, which may raise the intra-abdominal pressure and further limit working space. The potential for rhabdomyolysis, a rare but devastating complication in the obese as well as very muscular individuals undergoing prolonged procedures, must also be considered (Troppmann and Perez, 2003; Glassman et al, 2007).

Considerations in Elderly Patients

The ever-increasing use of laparoscopy in urology has demonstrated benefits in all patient populations irrespective of age. Laparoscopy has been shown to be safe and effective in elderly individuals (McDougall and Clayman, 1994), and its use is now commonplace

in patients of all age groups and risk stratification (Salami et al, 2013). The well-documented advantages of laparoscopy compared with open surgery including reduced postoperative pain, decreased analgesic requirements, and more rapid convalescence are particularly welcome in elderly patients who are often at higher risk of perioperative complications. Limited nutritional, pulmonary, and cardiovascular reserve relative to younger patients gives rapid convalescence particular importance in this patient population. Minimization of narcotic use, early mobilization, and physical therapy (when warranted) are important management principles in this patient population.

SURGICAL APPROACHES AND OBTAINING ACCESS

There are currently five laparoscopic approaches to renal surgery: transperitoneal, retroperitoneal, hand assisted, robotic, and laparo-endoscopic single-site surgery (LESS) and natural orifice transluminal endoscopic surgery (NOTES). Each approach can have discrete advantages and limitations depending on the patient factors, pathology and clinical situation, and surgeon familiarity with each approach. To date, no studies have shown a definitive recuperative advantage of any one of these approaches. Potential differences in cosmesis may exist, but have also not been consistently demonstrated thus far.

Transperitoneal Approach

The transperitoneal approach is the traditional and most widely used laparoscopic method of addressing renal pathology. It provides the largest working space, facilitates orientation by providing readily identifiable anatomic landmarks, affords greater versatility in angles and location of laparoscopic trocars and instruments, and can result in the smallest size and number of ports used. The equipment is mature and techniques are well defined, but as with any approach, it requires significant expertise in instrument manipulation and suturing.

Patient Positioning and Trocar Placement

For most transperitoneal renal surgery, the patient is initially positioned supine for intravenous (IV) access, the induction of general anesthesia, and endotracheal intubation. A urinary drainage catheter and an orogastric tube are placed for decompression of the bladder and stomach during insufflation, trocar placement, and dissection. Sequential compression stockings are placed for deep venous thrombosis prophylaxis. For transperitoneal procedures, including robotic-assisted laparoscopy surgery and LESS, patients are positioned in a 30- to 45-degree flank-up position. Care is taken to pad all pressure points to minimize risk of nerve injury and reduce the incidence of tissue breakdown and rhabdomyolysis. The patient is secured to the operating table to allow lateral tilting of the table (Fig. 61-1). Tilting the table away from the affected kidney will help move bowel out of the operative field. There is no need

Figure 61-1. The patient is placed in a modified flank position, with the operative side tilted up 30 to 45 degrees using a gel roll or a rolled blanket supporting the back. The lower arm is placed on a padded arm rest, and the other arm is flexed at the elbow and rested over the chest. Wide cloth or silk tape is used to secure the patient to the operating table to allow for table rotation during the surgery.

to flex the table or elevate the kidney rest as there is with open surgery. The equipment in the operating room is situated to maximize the use of space and allow all members of the surgical team to view the procedure (Fig. 61-2). The entire flank and abdomen are included in the field of skin preparation and draping, in case conversion to an open procedure is required.

Once a pneumoperitoneum is established, three to five trocars are initially placed to complete the dissection (Fig. 61-3). A variety of trocar configurations are effective for each type of renal procedure.

A 12-mm trocar is placed in the anterior axillary line at the level of the umbilicus. This trocar is used for instrumentation and the passage of sutures, bulldog clamps, or staplers to secure and divide hilar vessels. In shorter patients, this may be placed in the midline, halfway between the umbilicus and pubis. A 10-mm trocar is placed at the umbilicus for camera manipulation, and a 5- or 10-mm port is inserted in the midline 2 cm below the xiphoid process. In obese patients, all trocar sites are shifted laterally (see Fig. 61-3C). Additional trocars for retraction may be needed for visualization or assistance with organ entrapment (Fig. 61-4). Additional low midline 10- or 12-mm trocars can be used for assistants to retract or use clamps or stapler devices. This low midline port site can be extended at the end of the case as a low midline extraction site.

Retroperitoneal Approach

The retroperitoneal approach mimics open surgery because the peritoneal cavity is avoided. A potential space is created to visualize the surgical field. This approach may be preferred for selected cases of laparoscopic partial nephrectomy (LPN), cyst marsupialization, pyeloplasty, or renal biopsy or in patients who have had peritonitis or who have undergone multiple prior abdominal surgeries resulting in significant intraperitoneal adhesions.

Patient Positioning and Trocar Placement

With this approach, patients are placed in a full-flank position. Modest table flexion can help increase the distance between the ribs

Figure 61-2. The operating room configured for left nephrectomy. Two monitors allow the assistant to follow the procedure. The scrub technician (Tech) is positioned to easily assist with instrument passage and exchange.

Figure 61-3. Trocar sites for left-sided (A) and right-sided (B) procedures. A 12-mm trocar is placed lateral to the rectus at the level of the umbilicus, a second 10-mm trocar is placed at the umbilicus, and a 5-mm trocar is inserted in the midline between the umbilicus and the xiphoid process. C, In obese patients, all trocars are shifted laterally. Optional accessory subcostal, subxiphoid, and low midline trocar positions, which may be helpful for retraction, are also shown.

Figure 61-4. Options for additional trocar placement and instrumentation. A, Additional retraction during left-sided procedures can be accomplished with the use of a blunt instrument passed through a 5- or 10-mm trocar placed above the symphysis pubis, or a 5-mm instrument and retractor passed through a subcostal incision. B, In right-sided procedures, the liver and bowel can be retracted through a 3- or 5-mm trocar placed in the midline. C, In right-sided procedures, the liver and bowel can be retracted through a 5-mm trocar with a 5-mm instrument. An optional 10-mm lower midline trocar may also be placed for retraction, freeing the two other working hands for dissection.

and iliac crest to facilitate trocar placement. An axillary roll is required, and great care is taken in securing the patient to the bed. Arms may be secured on pillows or a purpose-built arm rest. A 15-mm transverse incision is made in the posterior axillary line, midway between the tip of the 12th rib and the iliac crest (Fig. 61-5A). After the dissection is deepened downward through the lumbodorsal fascia, the retroperitoneum is entered, and a working space may be developed using blunt dissection with the tip of a finger in the space between the psoas muscle and the kidney (Fig. 61-5B). A simple balloon created from two fingers of a size 8 or 9 glove may then be inserted and filled with CO₂ or saline, or alternatively, a purpose-built trocar with an integrated balloon may be

used to dissect the fat away from the overlying musculature. Either will further aid in developing the retroperitoneal working space (Fig. 61-5C). A Blunt Tip Trocar (US Surgical, Norwalk, CT) is then passed through the incision, and the trocar cuff is expanded and cinched to the skin to prevent leakage of CO₂ (Fig. 61-5D). An alternative entry approach involves entry with the 0-degree lens and visual obturator through the initial incision (Fig. 61-6A). Entry into the retroperitoneum may be confirmed by the appearance of the characteristic yellow retroperitoneal fat; insufflation is initiated, and blunt dissection using only the laparoscope is performed to develop a working space (Fig. 61-6B). Caution must be used not to enter too anteriorly because inadvertent peritoneal entry or colon injury

Figure 61-5. Trocar placement for retroperitoneal kidney surgery. A, With the patient in the full lateral position, the hips flexed, and the kidney rest elevated, a 15-mm incision is made 2 cm below the tip of the 12th rib, between the rib and the anterior superior iliac spine. B, The index finger is inserted through the incision and used for blunt dissection to create a hole from the skin through the muscle into the retroperitoneal space. If the finger is in the correct position, the surgeon should feel the smooth surface of psoas muscle and the lower pole of the kidney covered by Gerota fascia. C, To quickly create the working space, insert a balloon created from the finger of a size 8 or 9 glove, secured with silk suture over a simple red rubber catheter. The balloon is then filled with 600 to 800 mL of saline. D, A Blunt Tip Trocar (US Surgical, Norwalk, CT) is used to seal the trocar site. Because of its low profile, it will not obstruct the view or take up useful space in the retroperitoneum. The balloon and collar configuration eliminates the need for sutures and allows 360-degree rotation.

may occur; entering too posteriorly may result in bleeding from entry into the quadratus lumborum or psoas muscles. Once the working space has been established through either approach, pertinent structures may be identified for orientation and additional trocar placement. Typically, a 5-mm trocar is placed just off the tip of the 12th rib, and a 12-mm trocar is placed posteriorly and superiorly relative to the camera port, both under laparoscopic visualization (see Fig. 61-5A).

The greatest limitations of the retroperitoneal approach are the limited working space and more subtle anatomic landmarks. The smaller working space limits the distance between trocars, potentially leading to decreased triangulation and challenging hand positioning, similar to LESS procedures. Also, with the area of surgical dissection much closer to the lens, frequent smudging of the laparoscope tip may occur. If additional space is needed during the procedure, initial retroperitoneal access can be expanded to a transperitoneal approach by opening the peritoneum under direct vision.

Despite these limitations, the retroperitoneal approach may be preferred in some cases, and with adequate experience a wide variety of laparoscopic renal surgical procedures may be performed via this approach.

Modifications for Hand-Assisted Laparoscopy

Hand assistance offers a bridge between open surgery and pure laparoscopy (Nakada et al, 1997). It offers more intuitive assistance from the surgeon's hand in performing dissection and retraction, with simultaneous tactile feedback. Several manufacturers make devices for this purpose. An incision large enough for the hand must be created and can also be used as an extraction site at the culmination of the case. This technique may be advantageous for the novice laparoscopist and in treating patients with significant scarring around the kidney or in cases for which a difficult dissection is anticipated. Hand assistance may also be used in the event of an

Figure 61-6. A, Standing behind the patient, the surgeon initially develops a space bluntly between the psoas muscle and the kidney using the visual obturator with the 0-degree laparoscope through it. B, Together, they are used to bluntly push the peritoneum medially, creating a working space large enough to allow placement of additional trocars.

emergency, such as bleeding, by extending a trocar site and placing a hand port to assist in achieving vascular control and repair.

Patient Positioning and Trocar Placement

The patient positioning is similar to that for transperitoneal laparoscopic kidney surgery. The initial incision for the hand port is made through the skin and fascia and into the peritoneal cavity. Location will depend on handedness of the surgeon, operative side, and body habitus of the patient (Figs. 61-7 and 61-8). Care must be taken to avoid making the incision too large because leakage of the pneumoperitoneum may occur, making the procedure more difficult owing to decreased working space. Once the hand-assistance device is placed, the pneumoperitoneum is

Figure 61-7. Port placement for a right-handed surgeon for hand assistance. A, For a right-sided kidney, the hand-assisted device is placed in the right lower quadrant for insertion of the left hand, and dissection is performed with instruments in the right hand placed through an umbilical trocar. The camera is placed several centimeters above the umbilicus in the midline. On the right side, retraction of the liver is usually necessary to allow visualization and dissection of the renal hilum. A liver or bowel retractor can be placed through a subcostal trocar to assist with visualization or irrigation and aspiration. B, For the left kidney, the hand-assisted device and left hand are placed through a periumbilical incision, and dissection is performed with the right hand using an instrument placed in the subcostal margin just medial to the nipple. The camera is placed several centimeters lateral to the edge of the actual hand-assisted device (not the edge of the incision). Additional assistance can be delivered through the most lateral trocar site.

Figure 61-8. Port placement for a left-handed surgeon for hand assistance **A**, When operating on the right kidney, a left-handed surgeon places the hand-assisted port in the periumbilical location for insertion of the right hand. The working port for the left hand is placed lateral to the rectus muscle, in line with or just inferior to the level of the umbilicus. The camera is placed through a lateral trocar in the anterior axillary line. Additional assistance with retraction of the liver can be accomplished through a subcostal trocar. **B**, For a left-handed surgeon operating on the left kidney, the hand-assisted port is placed in the left lower quadrant for insertion of the right hand. The left hand works with the instrument passed through an umbilical trocar, and the camera is placed midway between the umbilicus and the xiphoid process. Additional assistance with retraction or aspiration can be accomplished through a fourth trocar placed at the subcostal margin.

established, and additional trocars are placed under direct laparoscopic visualization by passing the camera through the hand port.

There are some limitations in location of port placement, and the hand may potentially get in the way of visualization or dissection instrumentation. In addition, these devices exert 30 to 100 mm Hg of pressure on the arm, which may account for surgeons developing tingling, numbness, or pain in the forearm or hand (Monga et al, 2004; Ost et al, 2006).

Modifications for Robotic-Assisted Laparoscopy

The da Vinci computer-aided surgical system (Intuitive Surgical) has been used to perform what has commonly become known as *robotic surgery*. This device uses a computer system and a series of mechanical arms to translate surgeon movements to a laparoscopic platform. Instrument movement of right and left is preserved, as opposed to pure laparoscopic surgery, in which it is reversed. Also, hand-eye association is preserved, and a dual lens system provides 3-dimensional (3D) visualization with depth perception. The addition of intracorporeal instrument articulation facilitates fine dissection, suturing, and other challenging laparoscopic tasks. These additions have reduced the need for advanced laparoscopic skills, allowing more surgeons to offer a minimally invasive approach to their patients, albeit at increased cost. Whereas robotic procedures require a skilled bedside assistant and more trocars than standard laparoscopy, most laparoscopic renal procedures can be completed in a solo fashion using a mechanical endoscope holder and two working trocars (Wang and Bhayani, 2009). The robotic platform provides more surgeons the ability to offer a minimally invasive approach to patients and has increased the use of robotics relative to pure laparoscopic kidney surgery (Patel et al, 2013).

Patient Positioning and Trocar Placement

Patient positioning will depend, in part, on tumor location (in cases of partial nephrectomy) and choice of a transperitoneal or retroperitoneal approach. In addition, the point in the operation at which the robotic device is docked must be considered because additional table rotation is not possible with the robot docked. The entire procedure may be performed with the aid of the robot, or, as in cases of partial nephrectomy, the initial portions of the operation may be performed using standard laparoscopy, with use of the robot for hilar dissection or in some cases only for tumor excision and renorrhaphy.

Most surgeons report using a flank position with the table modestly flexed, although a modified flank position without flexing the table has also been described in several series (Deane et al, 2008; Benway et al, 2009a; Boris et al, 2009; Kaouk et al, 2012). Inclining the table may provide additional space at the back of the patient for the robot and other equipment (Fig. 61-9).

Robotic trocars for instrumentation and camera are used for the procedure in addition to bedside assistant ports. A port-in-port technique of robotic-assisted partial nephrectomy (RaPN) has also been described, wherein the robotic 8-mm ports are inserted through standard 12-mm ports (Aron et al, 2008). This arrangement allows use of 10-mm instruments via standard laparoscopy before and after docking the robotic platform. It may also be advantageous in the event of an intraoperative complication or robotic malfunction, when emergent conversion to pure laparoscopic surgery is necessary. The robot can be undocked and a standard laparoscopic procedure can be completed without requiring additional time to insert new ports or working through 8-mm robotic ports that preclude passage of larger instruments such as stapler devices or CT-1 or CT-X needles.

A three-arm configuration includes a total of four or five trocars: a 12-mm periumbilical camera port, an 8-mm subcostal robotic trocar in the anterior axillary line, an 8-mm robotic trocar in the posterior axillary line placed above the iliac crest, and one 12-mm assistant trocar in the low midline to allow passage of sutures, bulldog clamps, stapler devices, suction, or retraction. An additional 5- or 12-mm subxiphoid trocar may be used, if necessary, for

Figure 61-9. Operating room configured for left-sided robotic-assisted laparoscopic partial nephrectomy.

Figure 61-11. Laparoendoscopic single-site surgery performed using three low-profile trocars inserted through a single small extraction incision. A flexible laparoscope and flexible instrumentation may be used. (From Tracy CR, Raman JD, Cadeddu JA, et al. Laparoendoscopic single-site surgery in urology: where have we been and where are we heading? *Nat Clin Pract Urol* 2008;5:561–8.)

Figure 61-10. Trocar placement for robotic-assisted laparoscopic renal surgery. A, Three-arm system configuration. B, Four-arm system configuration. A, assistant trocar; C, camera port; R, robotic trocar.

additional bedside assistance, if the angle is more optimal (Fig. 61-10A). A four-arm configuration involves a total of five or six trocars, using the same general configuration as the three-arm technique, but shifting the robotic trocars to avoid clashing of the robot arms (Fig. 61-10B).

Laparoendoscopic Single-Site Surgery and Natural Orifice Transluminal Endoscopic Surgery

LESS refers to laparoscopic techniques that consolidate all ports within a single skin incision, often concealed within the umbilicus (Box et al, 2008). This approach to renal surgery has evolved with the goal of further improving cosmesis and reducing postoperative pain relative to standard laparoscopic surgery. Clustering standard laparoscopic ports, purpose-built homemade multichannel access devices, and commercially available multichannel working ports can be used, typically placed in the umbilicus or below the waistline to minimize visible scars (Rais-Bahrami et al, 2009; Kaouk et al, 2011). To date, virtually all extirpative and reconstructive renal procedures have now been performed via LESS.

Patient Positioning and Trocar Placement

A variety of accepted methods of positioning and trocar use have been reported and are currently used for LESS procedures. Modified flank and full-flank positions have been described, mirroring positioning for standard transperitoneal or retroperitoneal laparoscopic kidney surgery, respectively. Once the pneumoperitoneum has been established, one may cluster multiple traditional low-profile trocars close together within a single, small extraction incision (Fig. 61-11). Alternatively, newer purpose-specific access devices (Fig. 61-12) may be used in combination with conventional laparoscopic or flexible instrumentation. The devices are secured using preplaced fascial sutures or with an inner and outer ring drawn together with a cylindrical sleeve. Characteristics of various single-site access options are described in Table 61-1.

LESS approaches are technically challenging, largely because of the limited triangulation afforded by the clustering of instruments entering the intracorporeal working space, making LESS the most difficult of the minimally invasive techniques. To date, randomized series comparing LESS with conventional laparoscopy have demonstrated comparative improvement in postoperative pain and potentially decreased analgesic use and shorter hospitalization (Tugcu et al, 2010; Kurien et al, 2011; Richstone et al, 2013). Adapting LESS for the context of robotic assistance and other specialized instrumentation has gradually increased the application and dissemination of this approach to minimally invasive renal surgery (Autorino et al, 2013).

NOTES involves using a natural orifice to perform the entire operation. In the gastrointestinal (GI) and surgical literature, the

Figure 61-12. Purpose-specific device for laparoendoscopic single-site surgery. The TriPort system (Advanced Surgical Concepts, Bray, Ireland) allows for passage of multiple instruments through a single incision.

mouth, vagina, and rectum have been used to remove organs such as the appendix and gallbladder (Rao and Reddy, 2005; Zorron et al, 2007; Palanivelu et al, 2008). In renal surgery, to date, experience with pure NOTES surgery in humans is limited (Kaouk et al, 2009a). Several authors have reported a hybrid NOTES approach with standard laparoscopic assistance, using the vagina as an access and extraction site during nephrectomy (Branco et al, 2008; Alcaraz et al, 2011; Paparel and Golfier, 2012). More recently, development of successful transvesical renal surgery in animal models has been reported (Metzelder et al, 2009; Bin et al, 2012).

SIMPLE NEPHRECTOMY

Laparoscopic simple nephrectomy is indicated in the treatment of most benign renal diseases. **Renovascular hypertension that is not correctable with medication or angiographic repair** may be managed with simple nephrectomy. Patients with **chronic pain syndromes** may benefit from nephrectomy, including **symptomatic acquired renal cystic disease**, **autosomal dominant polycystic kidney disease (ADPKD)**, **chronic hydronephrosis not amenable to surgical repair**, and **loin pain-hematuria syndrome**. **Chronic infectious processes** that are recalcitrant to antibiotic therapy may also be approached laparoscopically, including **chronic refractory pyelonephritis**, **xanthogranulomatous pyelonephritis (XGP)**, and **renal tuberculosis**. These conditions are associated with higher rates of conversion to open surgery as a result of perinephric inflammatory changes and loss of tissue planes (Gupta et al, 1997; Ber-cowsky et al, 1999). In some cases, a subcapsular nephrectomy may be necessary to safely complete the procedure. Hand assistance may also be of benefit and avoid open conversion in cases involving dense scar tissue formation or inflammatory reaction (Rosoff et al, 2006). Successful retroperitoneal laparoscopic simple nephrectomy has also been reported in 30 of 31 patients with nonfunctioning kidneys secondary to tuberculosis (Lee et al, 2002). Other benign conditions that may call for nephrectomy include patients with a multicystic dysplastic kidney or a symptomatic failed renal transplant. Again, in this latter case, a subcapsular dissection may be required because of significant perinephric scarring.

Procedure

Reflection of the Colon

For a left nephrectomy and all renal surgery, the line of Toldt is incised from below the lower pole of the kidney inferiorly to above the spleen superiorly (Fig. 61-13). The inferior limit of this incision may be extended further inferiorly if the colon does not sufficiently reflect medially. The lienocolic ligament should be incised to allow the spleen to fall medially along with the pancreas and the colon (see Fig. 61-13). Care must be taken to avoid injuring the diaphragm with this maneuver. The thin colorenal attachments are incised and the colon is swept medially, taking great care to avoid making a hole in the colonic mesentery (Fig. 61-14). Mesenteric fat has a brighter hue of yellow compared with the retroperitoneal or Gerota fat, which allows for identification of the correct plane of dissection. If the operative field is not adequately visualized, a paddle retractor may be placed through an additional lower midline trocar to aid in retracting the colon, pancreas, and spleen medially (see Fig. 61-4A). Blunt and sharp dissection is necessary to move these structures off the anterior surface of the kidney and renal hilum.

During a right-sided nephrectomy, the peritoneal incision is carried medially and parallel to the lateral border of the vena cava and duodenum. A lateral (anterior axillary line) or high midline port may be needed to retract the liver anteriorly (see Fig 61-4B and C). Care must be taken to avoid thermal injury to the duodenum and gallbladder during incision of the peritoneal lining. Medial traction on the colon reveals colorenal attachments that must be divided to complete the colon reflection. Again, a low midline retractor may be helpful for visualization. A Kocher maneuver may be required to fully expose the medial portion of the kidney and the connective tissue overlying the renal hilum and inferior vena cava (Fig. 61-15). This should be done without electrocautery adjacent to the duodenum.

Dissection of the Ureter

Once the colon has been adequately mobilized, the psoas muscle and tendon should be identified inferior to the lower pole of the kidney. Following the psoas medially, the gonadal vessels are usually encountered first. These should be swept medially—the ureter is usually located just deep to these vessels. Peristalsis of the ureter can help differentiate between the ureter and adjacent vascular structures. **Once identified, the ureter is elevated and followed proximally to the lower pole of the kidney. The ureter is not divided at this time, because it can be used to help elevate the kidney (Fig. 61-16).** The tissue posterior to the ureter and lower pole of the kidney is swept anteriorly to further expose the anterior surface of the psoas muscle. Care should be taken to stay above the psoas fascia to minimize postoperative thigh numbness. The instrument in the subxiphoid trocar is used to slide under the kidney through to the sidewall. This allows the surgeon to lift the kidney anteriorly and laterally, placing medial lymphatic and vascular attachments on stretch.

Identification of the Renal Hilum

Safe dissection of the renal hilum requires medial retraction of the colon and bowel by gravity or an additional retractor, as well as anterior-lateral retraction of the kidney, lifting it out of the renal fossa. With the ureter and lower pole of the kidney elevated, vessels entering the renal hilum can be identified and bluntly dissected using the tip of the irrigator-aspirator. **Firm elevation of the kidney to provide hilar traction is a key principle of laparoscopic renal surgery and assists in identification and safe dissection of the renal hilar vessels (Fig. 61-17).** This is accomplished by gently placing the lateral grasper under the ureter and kidney until it abuts the abdominal sidewall. It is important to be sure that the grasper is against the muscle and not into the renal parenchyma. A gentle, layer-by-layer dissection is performed with the irrigator-aspirator until the renal vein is uncovered. There is usually an anterior

TABLE 61-1 Access Options for Laparoendoscopic Single-Site (LESS) Surgery

ACCESS TYPE	DESCRIPTION
Keyhole	Use of three closely approximated periumbilical trocars placed side by side in a single skin incision or three separate incisions. No additional purpose-built device required. Typically used with articulating camera and specialized instrumentation. Insufflation through one of the trocars.
TriPort +/-TriPort 15/QuadPort + (Advanced Surgical Concepts, Bray, Ireland)	Open or closed access, may be used with multiple incision sizes, typically 2.5- to 5-cm fascial incision. Anchored by inner (intra-abdominal) and outer rings drawn together with cylindric sleeve. Three-port (one 12-mm and two 5-mm) and four-port (two 12-mm and two 5-mm) configurations available. Insufflation through valve housing.
Uni-X (Pnavel Systems, Cleveland, OH)	Open access technique, requires 2-cm fascial incision. Anchored with preplaced fascial sutures. Single port encompassing three 5-mm access ports. Typically used with articulating camera and specialized instrumentation. Insufflation through valve housing.
GelPort/GelPoint (Applied Medical, Rancho Santa Margarita, CA)	Open access technique, requires 2.5- to 5-cm fascial incision. Anchored by inner and outer rings drawn together with cylindric sleeve. Can accommodate all trocar sizes. May allow for wider spacing of trocars. Insufflation through trocar placed through device.
AirSeal (SurgiQuest, Milford, CT)	Various trocar sizes up to 27 mm, oval-shaped trocar accommodating multiple instruments. High-velocity CO ₂ recycling system to maintain pneumoperitoneum pressures without mechanical valve.
SILS (Covidien, Mansfield, MA)	Single biconcave piece of foam with a valve for insufflation and three holes to accommodate trocars (three 5-mm low profile trocars or two 5-mm trocars and one 10- to 12-mm trocar). Inserted via open Hasson technique through minimum 2-cm fascial incision with the aid of a Péan clamp.
SPIDER (TransEnterix, Morrisville, NC)	Single-access device allowing for the use of flexible instruments passed through articulating instrument delivery tubes. Additional working channels allow for use of conventional laparoscopic instruments as well.
Homemade port (using Applied Medical [Rancho Santa Margarita, CA] wound retractor)	Similar to GelPoint trocar using a wound retractor from the same company in addition to a sterile surgical glove. Surgical glove secured to the wound retractor using suture or sterile rubber bands. Trocars can be passed through each of the fingers of the surgical glove portion of the access device.
OCTO Port (DalimSurgNET, Seoul, Korea)	Available in two base sizes requiring fascial incisions ranging from 1.5 to 5 cm. Uses a wound retractor and multiple attachments allowing for up to four ports.
Single Site Laparoscopy (SSL) Access System (Ethicon Endo-Surgery, Somerville, NJ)	Similar to other access devices in using a wound retractor base with an attachment cap. Integrates channels (two 5-mm instruments and a 10- to 12-mm instrument) with no trocar components protruding above the low-profile cap that can rotate. Placed through 2- to 4-cm fascial openings and able to traverse abdominal wall thickness up to 7 cm.

bundle of connective tissue that needs to be incised to fully expose and visualize the anterior surface of the vein. Gonadal, lumbar, and accessory venous branches can be clipped and divided as necessary.

Securing the Renal Blood Vessels

By clearing off inferior attachments and lymphatics, one can identify the renal artery, most commonly posterior to the vein. Care should be taken to identify the location and number of renal arteries based on preoperative imaging as available. If the irrigator-aspirator tip is not precise enough for meticulous dissection, a hook electrode or laparoscopic DeBakey forceps can be used to dissect the lymphatic

vessels free of the vein and artery. **With an endovascular gastrointestinal anastomosis (GIA) stapler, first the artery is ligated and divided, then the vein (Fig. 61-18).** In some instances clips may be needed, in which case multiple clips are recommended on the remnant patient-side of the vessels. In 2006 and 2011, the manufacturer of Weck Hem-o-lok Ligating Clips (Teleflex Medical) and the Food and Drug Administration respectively issued alerts stating that **Weck Hem-o-lok Ligating Clips are contraindicated for the ligation of the renal artery** during laparoscopic donor nephrectomy owing to several donor deaths linked to failure of the clips in ligating the vessel. Given these recommendations, we advocate for the use of either vascular stapling devices or multiple titanium clips for the ligation of the renal artery in all laparoscopic renal surgery.

Figure 61-13. Incision of the white line of Toldt with endoshears, bipolar cautery, or ultrasonic energy allows reflection of the colon. Continuing superiorly allows incision of the lienocolic ligament, facilitating reflection of the spleen, pancreas, and colon.

Figure 61-14. Medial traction on the colon helps identify additional colorenal attachments and assists in differentiating the undersurface of the large bowel mesentery. Care must be taken at this step to avoid creating a mesenteric window.

Isolation of the Upper Pole

Once the hilar vessels have been divided, the dissection continues posteriorly and superiorly to the upper pole. The adrenal gland is preserved in cases of simple nephrectomy by staying close to the upper pole (Fig. 61-19). This is accomplished by incising the Gerota fascia anteriorly, just above the hilum. The perinephric fat is then gently peeled off circumferentially above the upper pole of the kidney. At this point during the dissection, it may be necessary to clip and transect the ureter. This allows the kidney to be rotated anteriorly above the liver (right) or spleen (left) to facilitate incision of the uppermost attachments under direct vision. In cases of

Figure 61-15. On the right side, the colon is reflected, and a Kocher maneuver may be performed to completely expose the kidney and the renal hilum.

Figure 61-16. A curved dissector, in the left hand, is placed beneath the ureter and used to provide anterolateral elevation. On the right side the angle of insertion from the gonadal vein to the vena cava can be a source of significant bleeding if torn during elevation.

extreme fibrosis, a subcapsular nephrectomy can be performed once the artery and vein have been controlled (Moore et al, 1998). Long, blunt instruments, such as the 10-mm LigaSure Atlas (Valleylab, Boulder, CO), are particularly well suited for reaching and bluntly dissecting free the upper pole attachments. Care should be taken to avoid a diaphragmatic injury. Once the upper pole is free, the ureter can be ligated and lateral attachments taken with electrocautery.

Organ Entrapment and Extraction

The kidney can be removed intact or through morcellation. When morcellation is performed in cases of malignancy, the specimen

Figure 61-17. The lower pole of the kidney and ureter are firmly retracted anterolaterally, placing the hilum on stretch. The left gonadal vein has been ligated and divided.

A

B

Figure 61-18. A, First, the renal artery is stapled using an endovascular gastrointestinal anastomosis (GIA) stapler. B, The renal vein is secured lateral to the adrenal vein with the GIA stapler. If clips are used on the gonadal or adrenal vessels, the surgeon must be careful to exclude them from the jaws of the stapler.

Figure 61-19. The adrenal gland can be preserved during simple nephrectomy or radical nephrectomy as indicated by dissecting it from the superior pole of the kidney.

should be placed into a sturdy entrapment sac (Urban et al, 1993). This minimizes the risk of rupture during mechanical morcellation of the tissue (Landman et al, 2000a; Pautler et al, 2002). With use of ring forceps and a Kocher clamp, the kidney and collecting system can be morcellated and removed in small pieces (Fig. 61-20). Purpose-built morcellators have become increasingly controversial owing to rare cases of port-site metastasis or tumor spread during surgery when malignancy is unsuspected. If used, great care must be taken to avoid engaging other organs or leaving tissue behind. Alternatively, the kidney can be removed intact through an incision after placement into a sac (Fig. 61-21). The kidney can be worked out of an extended trocar site or Pfannenstiel incision.

Postoperative Management

The orogastric tube is removed at the conclusion of the procedure. The patient can begin a diet as tolerated. The Foley catheter should be removed once the patient is comfortably ambulating. Depending on patient reliability and surgeon preference, the patient may be discharged either when tolerating a regular diet in the hospital or with instructions to begin a regular diet at home once passing flatus. Unrestricted activity can usually be resumed according to patient comfort, although in patients with an extraction incision, heavy lifting is often restricted until after 4 to 6 weeks of convalescence.

Results

The postoperative results of laparoscopic nephrectomy are comparable to those of open surgery, with less pain and shorter convalescence. Postoperative pain control requirements are approximately four times less than with traditional open incisions. Hospital stays have been decreased by 50%, and the time to full convalescence has been reported to be markedly less than with open removal. In early series, the mean operative times were greater than 300 minutes. However, with advances in technique, experience, and equipment, current operative times have decreased dramatically (Kerbl et al, 1994b; Nicol et al, 1994; Parra et al, 1995; Baba et al, 1996; Rassweiler et al, 1998a).

SURGERY FOR RENAL CYSTIC DISEASE

Renal cysts are extremely common and are present in more than one third of patients older than 50 years (Laucks and McLachlan, 1981; Carrim and Murchison, 2003). They rarely require surgical intervention, but indications include cyst-associated pain, infection, or obstruction (Hoenig et al, 1997; Wolf, 1998; Roberts et al,

Figure 61-20. Removal of the morcellated specimen. A, The LapSac (Cook Urological, Spencer, IN) entrapment sac is introduced through the lateral 10-mm trocar site after passage of a hydrophilic wire through the opening of the LapSac. The entrapment sac is then released within the abdomen. The wire facilitates opening of the bag and placement of the specimen. A lateral 5- or 3-mm port may be necessary to assist with holding placement of the specimen inside the LapSac. B, Once the specimen is within the LapSac, the wire is removed, the bag cinched closed, and the opening withdrawn through the 10-mm trocar site. C, The entrapment sac is pulled tightly up against the abdominal wall, with two hands pushing part of the specimen to appear through the opening of the LapSac. After the site is carefully draped, manual morcellation with ring forceps or a Kelly clamp can be used. D, The entrapment sac is removed once the remaining specimen fragments are small enough to be extracted through the trocar site. Only the tissue visible from the opening is grasped. Blind passes into the bag may injure surrounding bowel segments.

Figure 61-21. Removal of the intact specimen. **A,** The camera is moved to the lateral port site and an Endo Catch device (Covidien, Dublin, Ireland) is placed through the umbilical trocar site to entrap the specimen. **B,** Alternatively, the specimen may be extracted through a Pfannenstiel incision. To accomplish this, the Endo Catch device is brought in through a separate 10-mm suprapubic incision. **C,** The trocar is then removed, bringing the Endo Catch device with it through the trocar site, and the suture is cut and clamped. **D,** A 4- to 6-cm incision is made including one of the trocar sites. The surgeon's finger protects the specimen and underlying structures from injury.

TABLE 61-2 Renal Cyst Classification Based on Updated Bosniak Criteria

TYPE	DESCRIPTION	RECOMMENDED MANAGEMENT
I	A benign simple cyst with a hairline thin wall that does not contain septa, calcifications, or solid components. It measures water density and does not enhance.	No follow-up necessary
II	A benign cyst that may contain a few hairline thin septa in which “perceived” [*] enhancement may be present. Fine calcification or a short segment of slightly thickened calcification may be present in the wall or septa. Uniformly high-attenuation lesions (3 cm) (so-called high-density cysts) that are well margined and do not enhance are included in this group.	No follow-up necessary
II F	Cysts that may contain multiple hairline thin septa or minimal smooth thickening of their wall or septa. Perceived enhancement of their septa or wall may be present. Their wall or septa may contain calcification that may be thick and nodular, but no measurable contrast enhancement is present. In general, these lesions are well margined. Totally intrarenal nonenhancing high-attenuation renal lesions >3 cm are also included in this category.	Follow-up imaging required
III	“Indeterminate” cystic masses that have thickened irregular or smooth walls or septa in which measurable enhancement is present. These are surgical lesions, although some will prove to be benign (e.g., hemorrhagic cysts, chronically infected cysts, and multiloculated cystic nephroma) and some will be malignant, such as cystic renal cell carcinoma and multiloculated cystic renal cell carcinoma.	Surgical treatment
IV	These are clearly malignant cystic masses that can have all the criteria of category III, but also contain enhancing soft-tissue components adjacent to, but independent of, the wall or septum. These lesions include cystic carcinomas and require surgical removal.	Surgical treatment

From Israel GM, Bosniak MA. An update of the Bosniak renal cyst classification system. *Urology* 2005;66:484–8.

^{*}Not measurable enhancement.

2001; Doumas et al, 2004; Camargo et al, 2005). The increased use of cross-sectional imaging has also increased the detection of indeterminate renal cystic lesions and complex renal cysts, bringing an increased number to the attention of urologists. Classification schemata have been developed to help clinicians make determinations regarding management, the most popular being the Bosniak system (Table 61-2) (Israel and Bosniak, 2005). Although this imaging schema can be extremely useful, they are not always diagnostic, and surgery may be required in some cases to exclude malignancy.

First-line therapy and diagnosis of symptomatic renal cysts often involve percutaneous image-guided needle aspiration, with or without the use of a sclerosing agent, to reduce risk of recurrence. If symptoms temporarily resolve and recur when fluid reaccumulates, this increases the likelihood that surgical treatment will be successful in resolving the pain (Rané, 2004). Caution should be exercised in use of cyst aspiration and sclerosing agents in peripelvic cysts, because fibrosis may occur (Wehle and Grabstald, 1986; Hulbert et al, 1988; Santiago et al, 1998; McDougall, 2000).

In addition to causing pain, cysts may compress the renal parenchyma or other adjacent organs, cause ureteral obstruction and obstructive uropathy, spontaneously bleed, cause hypertension, or become infected. Laparoscopic cyst decortication or unroofing may be used to treat these cysts, which are typically simple in character (Fig. 61-22). Cysts with complex appearance, such as thickened septa, calcification, or enhancement (Bosniak class III to IV), may be explored and sampled laparoscopically to rule out renal cell carcinoma (RCC) owing to their increased risk of harboring malignancy (Cloix et al, 1996; Santiago et al, 1998). Options include cryoablation, enucleation, partial nephrectomy, and radical nephrectomy. If there is any question of cyst proximity to the collecting system, cystoscopy and placement of an open-ended ureteral catheter may be performed to ensure the integrity of the collecting system after cyst excision via partial nephrectomy.

A subset of patients with ADPKD may develop cyst-associated pain. Laparoscopic cyst decortication, marsupialization, or unroofing can be of benefit to these patients by offering a minimally invasive treatment that is successful in relieving pain in up to 83% of cases (Lifson et al, 1998; Dunn et al, 2001; Lee et al, 2003).

Figure 61-22. Axial computed tomography scan in delayed phase after intravenous contrast administration, demonstrating peripelvic cysts in a patient with left flank pain.

In patients with end-stage renal disease, bilateral synchronous laparoscopic nephrectomy may be performed in patients with enlarged, symptomatic, or infected kidneys (Gill et al, 2001; Rehman et al, 2001; Bendavid et al, 2004; Desai et al, 2008; Martin et al, 2012). Because an incision will be required to remove kidneys that are often quite enlarged, a hand port may be placed in the midline and used bilaterally to facilitate the dissection (Rehman et al, 2001; Jenkins et al, 2002; Eng et al, 2013).

Procedure

Depending on cyst location, a transperitoneal or retroperitoneal approach may be used as previously described. Intraoperative ultrasonography may be used to identify the cyst or cysts in question. It is usually easier to dissect the cyst wall free of surrounding

Figure 61-23. The cyst fluid is aspirated with a laparoscopic aspiration needle. After decompression of the cyst, the wall can easily be grasped and manipulated. The cyst is elevated with a grasper and scissors or ultrasonic shears to circumferentially excise the cyst wall. The edge of the cyst is carefully inspected, and biopsies are performed using the 5-mm laparoscopic biopsy forceps as needed.

connective tissue before evacuating fluid. The wall of the cyst can then be grasped and excised, cutting along the junction between the cyst wall and the renal parenchyma (Fig. 61-23). If suspicious lesions are noted in the base, biopsy specimens may be taken using the 5-mm biopsy forceps. If no evidence of malignancy is seen, the remaining cyst wall may be fulgurated with either electrocautery or the argon beam coagulator. Care should be taken when ablating the surface, because inadvertent or occult entry into the collecting system can easily occur (Cherullo et al, 1999). Moreover, these surfaces can be friable and prone to significant bleeding. Packing with hemostatic agents or suturing may be necessary. One should have a low level of suspicion for entry into the collecting system and therefore a low threshold for leaving a drain (Fig. 61-24). If malignancy is noted, extirpative surgery or cryoablation may be used to treat the remainder of the lesion.

When treating central or perihilar cysts, it may not be feasible to remove a large portion of the cyst wall. In these cases, it is helpful to place a pedicle of autologous fat into the defect to act as a wick (Nieh and Bihrlé, 1993).

Results

Laparoscopic treatment of symptomatic renal cysts has been found to be effective in both decompression and pain control. A study evaluating treatment durability at a mean follow-up of 26 months demonstrated a 100% pain-free rate in patients treated for a solitary symptomatic renal cyst (Lifson et al, 1998). In a separate study with a mean follow-up of 60 months, 80% to 90% of patients had complete resolution of pain after laparoscopic cyst decortication. In patients with ADPKD, additional benefits of cyst decortication have been noted, including decreased blood pressure (Dunn et al, 2001; Lee et al, 2003). Recurrence of pain in this group is higher than in patients with simple cysts, and durability is moderate (Brown et al, 1996). No significant changes in renal function were noted postoperatively.

Patients undergoing surgery for cystic renal disease are inherently a heterogeneous group, made up of patients with simple renal cysts, complex or indeterminate cysts, and ADPKD. Interpretation

Figure 61-24. Drain placement after renal cyst excision. If the collecting system has been entered, it is closed and a drain placed. To insert the drain, a hemostat is passed through a small stab incision in the side and advanced into the abdominal cavity under direct vision. A drain is placed through a trocar site and advanced toward the open hemostat using the trocar to direct the drain. The colon is brought back over the kidney and attached to the sidewall to “reperitonealize” the kidney and drain.

of incidence reports of RCC in these series must take this fact into account. That said, the reported incidence of RCC in cystic lesions is 3% to 20% (Rubenstein et al, 1993; Lifson et al, 1998; Roberts et al, 2001; Limb et al, 2002).

RENAL BIOPSY FOR MEDICAL RENAL DISEASE

Histologic information is a key component in making treatment decisions and for prognosis in patients with proteinuria or unexplained renal insufficiency (Morel-Maroger, 1982; Gault and Muehrcke, 1983; Manaligod and Pirani, 1985). Although the modality of choice is typically ultrasound-guided or CT-guided percutaneous renal biopsy, laparoscopic biopsy may be preferred in certain situations, such as failed attempts at percutaneous biopsy, renal anatomic anomalies hindering image-guided percutaneous biopsy, heightened risk of bleeding complications, morbid obesity, multiple renal cysts, or a solitary kidney.

Procedure

The patient is placed in the full-flank position with the table flexed to increase working space between the costal margin and the iliac crest. Retroperitoneal access is preferred and obtained using techniques described earlier in this chapter. Renal biopsy is accomplished with the use of two trocars. With blunt dissection, the Gerota fascia is opened, and the lower pole of the kidney is exposed (Fig. 61-25A). In obese patients, intraoperative ultrasonography may be required to localize the kidney when copious retroperitoneal or perinephric fat is present. Five-millimeter biopsy forceps are used to take samples of cortical tissue; hemostasis is achieved with Bovie electrocautery or the argon beam coagulator; and adjunctive hemostatic measures are used as necessary (Fig. 61-25B).

Results

A multi-institutional series reporting on outcomes of laparoscopic renal biopsy in 74 patients over 9 years showed a mean operative

Figure 61-25. A, After establishment of a working space, a 5-mm trocar is placed under direct vision. The working instruments are passed through this port. The camera can be used to assist with dissection and is frequently cleaned to maintain adequate visualization. B, Gerota fascia is opened with the use of the scissors. With 5-mm two-tooth laparoscopic biopsy forceps, two or three samples are taken from the lower pole of the kidney.

time of 123 minutes, mean estimated blood loss of 67 mL, and discharge within 24 to 48 hours unless other preexisting medical conditions required a longer stay (Shetye et al, 2003). Tissue obtained from 96% of patients was adequate for diagnosis, with a complication rate of 13.5%. The authors concluded that laparoscopic renal biopsy may be performed safely with a high success rate, and that as experience grows, the complication rate and operative duration would likely decrease. In another series of 17 patients, use of balloon dilatation to create the working space demonstrated 100% success in obtaining renal tissue adequate for diagnosis. Mean operative time was 35 minutes (excluding anesthesia time), complication rate was 11%, and 15 of 17 patients were discharged within 24 hours. In published series of laparoscopic renal biopsy, hemorrhage is the most common complication. Caution should be used in resumption of anticoagulation in patients who require it postoperatively. If signs or symptoms of postoperative anemia or hypovolemia occur, a low threshold should be used to evaluate the patient with computed tomography (CT).

NEPHROPEXY

Renal ptosis, although rare, is a real cause of chronic flank or upper abdominal pain. The precise origin of symptoms is unknown but is likely secondary to either transient ischemia or urinary obstruction (Moss, 1997). The typical patient with a ptotic kidney is a young, thin female who complains of pain while in an upright position. Supine and erect intravenous pyelography (IVP) can be used for diagnosis, with the finding of interest being ptosis, defined as descent of the symptomatic kidney by two vertebral bodies (Fig. 61-26). Nuclear imaging may also quantify obstruction of blood flow or drainage in the upright position. Color Doppler sonography in both the supine and upright positions can also be used to evaluate differential blood flow. If a ptotic kidney is present, the expected finding would be diminished blood flow while in the erect position. Before surgical repair, obstruction, decreased blood flow, or significant descent correlating with pain should be documented.

Procedure

Surgical repair is performed using either a standard transperitoneal or retroperitoneal approach to fully mobilize the affected kidney and expose the fascia overlying the psoas and quadratus lumborum muscles (Chueh et al, 2002; Matsui et al, 2004) (Fig. 61-27). Beginning at the upper pole, interrupted sutures are placed to secure the lateral edge of the renal capsule to the fascia overlying the muscle (Fig. 61-28). Sutures may also be placed between the anterior renal capsule and the parietal peritoneum for additional support. Using sutures with preplaced Lapra-Ty clips (Ethicon, Cincinnati, OH), the initial pass is made through the fascia or peritoneum, and a second clip is placed on the suture after the pass through the kidney. An alternative technique describes the use of tension-free vaginal tape to secure the kidney (Hübner et al, 2004). By placement of the needles such that the tape is passed around the lower pole of the kidney and out through the abdominal wall, the kidney is secured. Sometimes this is found in conjunction with a ureteropelvic junction obstruction that should be addressed simultaneously (Boylu et al, 2009).

Results

A retrospective study of 30 patients undergoing laparoscopic nephropexy with a median follow-up of 5.9 years demonstrated improvement in all patients, 11 with complete relief of symptoms (Plas et al, 2001). Significant improvement in differential renal function was measured by renal scan in 9 of 10 patients undergoing the study postoperatively. Two patients developed a recurrent ptotic kidney with greater than 5 cm of descent documented by IVP. An additional study of 48 patients, with a median follow-up of just over 8

Figure 61-26. Intravenous pyelogram demonstrating bilateral ptotic kidneys in the supine (A) and standing (B) positions. (From El-Moula MG, Izaki H, Kishimoto T, et al. Laparoscopic nephropexy. *J Laparoendosc Adv Surg Tech A* 2008;18:230–6.)

Figure 61-27. The kidney is stripped of overlying Gerota fascia down to the surface of the renal capsule. All remaining attachments are divided, allowing full mobility for repositioning.

Figure 61-28. Nephropexy. Once the kidney is free of lateral and posterior attachments, multiple 2-0 sutures are placed into the capsule and the lateral edge of the fascia overlying the abdominal wall. Sutures may also be placed between the anterior renal capsule and the parietal peritoneum for additional support.

years, revealed that 94% of patients had no signs of significant ptosis on postoperative imaging, and 91% of patients had improvement in their pain symptoms (Gözen et al, 2008). Mean operative time was 95 minutes, and mean estimated blood loss was 50 mL. Patient satisfaction was high, and the authors concluded that laparoscopic nephropexy provided a minimally invasive approach to these patients with good long-term clinical outcomes. More recently, robotic assistance and LESS approaches to laparoscopic nephropexy have also been reported, mimicking similar techniques and reporting similar outcomes, although not directly compared with conventional laparoscopy (Boylu et al, 2009; Tsai et al, 2010; Baldassarre et al, 2011).

CALYCEAL DIVERTICULECTOMY

Patients with symptomatic calyceal diverticula containing stones can be managed laparoscopically. Extracorporeal shock wave lithotripsy (ESWL) and ureteroscopy may be used, but because of infundibular stenosis, stone clearance rates are low (Jones et al, 1991; Pang et al, 1992; Stream and Yost, 1992). The principles of treatment include the removal of stones and widening of the infundibular stenosis to prevent urinary stasis or performing ablation of the diverticula cavity altogether. In the past, symptomatic calyceal diverticula have been managed with partial nephrectomy, with marsupialization and fulguration of the diverticulum, and

occasionally with simple nephrectomy. More recently, percutaneous treatment has been used, but stones or symptoms may recur if the cavity is not fully ablated (Donnellan et al, 1999). A laparoscopic approach may be indicated with large, peripheral diverticula, or for centrally located diverticula with proximity to the renal hilum.

Procedure

The location of the diverticula will be the primary driver for choosing either a transperitoneal or a retroperitoneal approach. Once the renal dissection has been completed, locating the diverticulum may prove difficult. Dense adhesions on the surface of the kidney overlying the diverticulum may be present along with a “dimpling” effect on the renal capsule. Intraoperative ultrasonography may also be used to aid in the location of the diverticulum or to confirm a suspected location. Once localized, the overlying parenchyma is incised and opened to expose the diverticulum, which is subsequently opened with cautery. Stones within the cavity may then be removed, and the argon beam coagulator or monopolar cautery device can be used to fulgurate the diverticular lining. The infundibulum in communication with the collecting system is closed with suture, and perirenal fat may be placed into the defect to further decrease the likelihood of recurrence. A drain is usually left in place after closure of the collecting system defect.

Results

Published reports on laparoscopic calyceal diverticulectomy are limited to small series and case reports. Excellent results have been reported by numerous authors, demonstrating the definitive nature of this treatment modality (Gluckman et al, 1993; Ruckle and Segura et al, 1994; Harewood et al, 1996; Wolf, 2000; Miller et al, 2002; Canales and Monga, 2003; Wyler et al, 2005; Gonzalez et al, 2011). Probably due to the rarity of this surgery and small case series in the literature, complications are also rare and not consistently reported.

NEPHROLYSIS

Nephrolysis has been used to treat loin pain, hematuria syndrome, and chyluria. The first indication has limited data. Chyluria is caused by lymphatic rupture or fistulous connection into the pyelocalyceal system. It is a rare problem worldwide but is commonly seen in tropical countries where filariasis (*Wuchereria*

bancrofti or *Brugia malayi*), the most common cause, is endemic (Tandon et al, 2004). Rarely, schistosomiasis may also be a cause of chyluria, and nonparasitic chyluria is rare. Other reported causes include tuberculosis (Wilson and White, 1976), idiopathic lymphorenal fistula (Eisner et al, 2009), prior surgery (Kim and Joudi, 2009), pregnancy (Onyeije et al, 1997), thoracic duct obstruction (Garrido et al, 1995), mesenteric adenitis (Cohen et al, 1984), renal vasculitis (El-Reshaide et al, 1998), and metanephric adenoma (McNeil et al, 2008).

Diagnosis of Chyluria

Patients typically have milky white urine and may have nephrotic range proteinuria. Initial evaluation includes urinalysis and culture, urine for chyle, and complete blood count to check for eosinophilia. Evaluation to localize the fistula may include cystoscopy with retrograde pyelogram, CT, magnetic resonance imaging (MRI), or lymphangiography (Fig. 61-29).

Treatment

Chyluria is often self-limited, and many patients may be managed conservatively. In filariasis-associated cases, this involves treatment with a course of diethylcarbamazine (DEC) in combination with a low-fat diet (Tandon et al, 2004). Retrograde instillation of silver nitrate or povidone iodine into the collecting system as a sclerosing agent has also been described, and these agents are commonly used as first-line treatment with comparable success rates of approximately 80% (Dalela et al, 2004b; Goel et al, 2004). When conservative management fails or if cases are particularly severe, surgical intervention is undertaken.

Procedure and Results

Nephrolysis involves the complete mobilization of the kidney and skeletonization of the renal hilar vessels and upper ureter with ligation of the lymphatic channels. The procedure may be performed laparoscopically with either a transperitoneal or a retroperitoneal approach and ensures complete lymphatic dissociation of the affected kidney (Chiu et al, 1995; Gomella et al, 1998). The use of an omental wrap around the hilum has also been described to provide an additional barrier against recurrence (Dalela et al, 2004a). It has been reported to be safe and efficacious even in the context of complex renal vasculature (Zhang et al, 2012). Authors commonly performing this procedure report excellent success rates approaching 100%.

RADICAL NEPHRECTOMY

Laparoscopic approaches to malignancy have been performed for over 20 years. The oncologic indications for laparoscopic radical nephrectomy (LRN) are similar to those for open surgery. Kidneys with tumors as large as 25 cm have been successfully removed laparoscopically, and cytoreductive nephrectomy has been performed in patients with metastatic disease (Walther et al, 1999). Moreover, tumors with caval thrombi have also been removed (Martin et al, 2008; Hoang et al, 2010; Bansal et al, 2014).

Transperitoneal

Procedure

Access and trocar placement are similar to what has been described for simple nephrectomy. With larger masses, caval involvement, or organ invasion, additional trocars or a hand port may be needed. The procedure for LRN is essentially identical to laparoscopic simple nephrectomy. The main distinguishing feature is that the Gerota fascia and fat are left intact during dissection. The adrenal may be removed en bloc with the kidney when indicated (Fig. 61-30A). To aid in this, the renal vein is taken medial to the take-off of the adrenal vein. In adrenal-sparing surgery, the fascia is opened over the upper medial aspect of the kidney (Fig. 61-30B). Suspect lymph nodes may be removed, and a full hilar or retroperitoneal dissection can be carried out if deemed necessary based on preoperative imaging, tumor location, and histologic subtype if known based on preoperative biopsy, prior surgery pathology, or hereditary predisposition. Excision of part of the adjacent muscle or involved organ, such as the diaphragm, pancreas, liver, spleen, and

bowel, has also been reported (Molina et al, 2004; Huscher et al, 2012).

Results

Long-term cancer-specific survival data are now widely available from multiple centers around the world that perform LRN (Table 61-3). Five- and 10-year outcomes show oncologic equivalence to open radical nephrectomy in treatment of renal cancer. Indeed, LRN has become the standard of care for most renal malignancies previously treated with open radical nephrectomy.

A multi-institutional study from centers performing LRN compared the surgical and disease-specific outcomes between open and LRN, with long-term follow-up (Portis et al, 2002). Median follow-up was 54 months, and recurrence-free survival rates were 91% and 92%, respectively, for the two groups at 5 years. The 5-year cancer-specific survival was 98% for the laparoscopic cohort and 92% for the open cohort.

A comparative analysis of 67 patients undergoing LRN, with 54 patients undergoing open radical nephrectomy, evaluated perioperative and oncologic outcomes (Permpongkosol et al, 2005). The LRN group showed a longer mean operative time (256 vs. 193 minutes). However, this finding likely reflects the learning curve for laparoscopy, because the first 34 patients and last 33 patients in the LRN group had a significant operative time difference. Complications occurred in 15% of patients in the LRN and open groups, and blood transfusions were required in 6% and 20% of the patients, respectively. Most important, the calculated disease-free survival rates for laparoscopic and open radical nephrectomy were 95% and 89%, respectively, at 10 years. The actuarial survival rates for laparoscopic and open radical nephrectomy were 87% and 75%,

Figure 61-30. A, Inclusion of the adrenal gland during right laparoscopic radical nephrectomy can be readily accomplished using ultrasonic or bipolar shears to control the multiple arterial branches to the adrenal gland. Inferior retraction of the specimen facilitates exposure of this surgical plane. B, Adrenal-sparing, right radical nephrectomy. Use of a blunt instrument above the hilum to put anterior and inferior traction on the kidney helps to expose the correct plane and place the connective tissue on stretch. Ultrasonic or bipolar shears are again useful to avoid any bleeding that may be encountered in this plane.

respectively, at 10 years. These differences were not found to be statistically significant.

More recently, 10-year oncologic outcomes data following LRN were reported. Recurrence-free, cancer-specific, and overall survival rates were 86%, 92%, and 65%, respectively, at 10 years postnephrectomy (Berger et al, 2009). Of 73 patients undergoing LRN, no patient developed local recurrence, and 6 (8.2%) developed metastatic disease at a mean time to recurrence of 74 months. Although outcomes in this study were not compared with an open radical nephrectomy cohort, results are quite comparable to those for open surgery.

Perioperative outcomes in contemporary groups undergoing laparoscopic and open radical nephrectomy have also been extensively studied. In a report comparing minimally invasive radical nephrectomy with open radical nephrectomy in the National Surgical Quality Improvement Program database, 5459 radical nephrectomy cases were identified. Significantly lower operative times, need for blood transfusion, length of hospitalization, and postoperative complications were noted in the laparoscopic patient cohort (Liu et al, 2014a). Similarly, in a well-matched cohort comparing laparoscopic with open radical nephrectomy, the laparoscopic approach was shown to have less blood loss, shorter hospital course, lower analgesic requirement, and shorter return to convalescence (Gill et al, 2000). Consistently, similar findings have been reported by multiple authors over the past three decades (Kerbl et al, 1994a; McDougall et al, 1996; Hemal et al, 2007).

Retroperitoneal

Procedure

The patient is positioned, and trocars are placed for retroperitoneal access as described earlier in the chapter. After identification of the psoas muscle and tendon, medial dissection in this plane will reveal the ureter. Elevation of the ureter will allow visualization and subsequent elevation of the lower pole of the kidney. This will place the main renal vessels on stretch, facilitating their dissection. The arterial pulsation may be indirectly visualized through overlying connective tissue, and just as with the transperitoneal approach, gentle layer-by-layer dissection with the suction-irrigator will allow the renal vessels to come more directly into view. Use of the right-angle dissector will allow the artery to be circumferentially freed from the surrounding tissue, and the endovascular stapler or clips are used to divide the artery and vein sequentially. During surgery on the left kidney, a lumbar vein will typically require dissection, ligation, and division to allow unencumbered access to the main hilum. Care must be taken to continuously reorient to anatomic relationships to ensure that the inferior vena cava is not mistakenly identified as the renal vein.

Results

When compared with transperitoneal LRN, outcomes of the retroperitoneal approach are similar with regard to complication rates, analgesic requirements, hospital course, and return to convalescence.

A randomized study comparing transperitoneal and retroperitoneal laparoscopic approaches was performed in 102 patients (52 transperitoneal, 50 retroperitoneal) with a mean tumor size of 5 cm (Desai et al, 2005). No difference was seen in blood loss, narcotic requirement, hospital stay, or complication rate. However, there was a significant difference noted in operative time, which favored the retroperitoneal approach (150 vs. 207 minutes). A second randomized study of 40 patients compared the number and size of trocars, pathologic stage, blood loss, operative time, complication rate, and hospital stay (Nambirajan et al, 2004). No statistical difference was noted in any of these outcomes, including operative time. A recent systematic review including prospective randomized controlled trials as well as retrospective observational studies comparing the outcomes of the two approaches demonstrated no significant difference in operative times, time to first oral intake, postoperative

analgesic requirement, postoperative complications, open conversion, need for blood transfusion, or oncologic outcomes (Fan et al, 2013).

Hand-Assisted

Procedure

The patient is positioned, and the hand port and trocars are placed as previously described. The steps in hand-assisted laparoscopic nephrectomy (HALN) are similar to those for pure laparoscopic surgery, but the nondominant hand is used throughout for retraction and blunt dissection. To incise the white line of Toldt, the nondominant hand retracts the colon medially while the dominant hand uses laparoscopic scissors to divide the attachments (Fig. 61-31). The irrigator-aspirator is then used to help identify and dissect the correct plane posterior to the large bowel mesentery and anterior to the Gerota fascia. The surgeon's hand and fingers may be used to simultaneously place lateral traction on the kidney and medial traction on the bowel, helping to demonstrate the correct plane. For a left-sided renal procedure, the hand may also be used to gently retract the spleen and pancreas medially while the lienorenal attachments are divided. Similarly, on the right, the hand is used to retract the liver anteriorly, exposing the upper pole and facilitating its dissection.

After the colon is sufficiently mobilized, the psoas muscle is identified, which will allow the ureter to be elevated. On the left the gonadal vein is typically elevated in the packet along with the ureter, but on the right the gonadal vein is reflected medially. With the ureter elevated, the hand can bluntly dissect and elevate the entire kidney off the psoas muscle, and the ureter is then followed up to the renal hilum. The fingers are then used to place anterolateral traction on the kidney while the thumb pushes the bowel and mesentery medially. The hilum should begin to come into view at this point, and the irrigator-aspirator can be used to gently dissect the overlying connective tissue while the hand is used to keep the vessels on stretch. Once the vessels are sufficiently skeletonized, the endovascular stapler or clips are used to ligate and divide the artery

Figure 61-31. The nondominant hand is used to retract the colon medially and to dissect tissue planes, while the dominant hand uses endoscopic scissors to divide colon attachments.

Figure 61-32. A, With the renal hilum on stretch and the bowel retracted medially to expose the vessels, the fingers can be used to palpate the renal artery and guide a stapler or clip applicator to secure and divide the artery. B, Once the artery is divided, the renal vein is freed circumferentially and divided with an endovascular stapler.

and vein sequentially (Fig. 61-32). The lateral and superior attachments may then be divided, using a LigaSure device or Harmonic scalpel (Ethicon) while the hand keeps them on traction. The hand should not be used to bluntly dissect the adrenal gland free from the upper pole of the kidney, because this will typically result in bleeding. Ultrasonic energy, LigaSure, or bipolar cautery may be used to divide the fragile attachments between the kidney and the adrenal gland, just as with pure laparoscopy.

A rolled laparotomy sponge is often placed through the hand port at the beginning of the procedure to assist with retraction, absorb blood, and allow the surgeon to hold pressure if needed. In addition, the tip of the irrigator-aspirator can be placed into the compressed sponge to facilitate suction when needed. It is critical to remember removal of the sponge at the end of the case. The previously made hand-port incision allows rapid removal of sponge and the intact specimen. However, hand-port metastases have been

reported, and it is recommended to place the specimen in a removal device before extraction to minimize any possibility of direct contact of the extraction specimen with wound edges.

The inserted hand can also facilitate closure of trocar sites greater than 10 mm with a suture-passing device. Wound complications such as hernias and infections have been reported at the hand-port site, with hernias typically manifesting 3 months or more after surgery and with an overall 4% incidence (Okeke et al, 2002; Wolf, 2005). Care must be taken to copiously irrigate and close the hand-port incision, ideally closing the peritoneum separately from the fascia to minimize the chance of injuring intraperitoneal structures and hernia formation.

Results

Most outcomes are comparable between pure laparoscopy and the hand-assisted technique, including efficacy, operative times, complication rates, narcotic requirements, length of hospital stay, and return to convalescence. Some comparative studies between laparoscopic and hand-assisted techniques have demonstrated that the hand-assisted procedures can require shorter operative times, but patients had more abdominal pain and wound complications (Nelson and Wolf, 2002).

Comparative studies between HALN and standard laparoscopic approaches have shown that choice of approach does not affect oncologic outcome. Gabr and colleagues (2009) studied and compared 147 patients who underwent standard laparoscopic nephrectomy and 108 who underwent HALN. Patients were followed for a mean of 35.2 months, and multivariate analysis showed that the approach did not affect recurrence-free, cancer-specific, or overall survival. A multi-institutional study of 95 patients undergoing HALN evaluated the impact of tumor size on outcome (Stifelman et al, 2003). Patients were grouped into those with tumors larger than 7 cm and those with tumors smaller than 7 cm. Short-term outcomes at mean follow-up of 12 months were not different between the two groups, including positive margin rate, local recurrence, and metastasis.

Special Considerations

Large Tumors

Experience with laparoscopy for large tumors (>7 cm) has grown substantially as confidence with renal laparoscopy has increased (Steinberg et al, 2004; Hemal et al, 2007; Berger et al, 2008; Rosoff et al, 2009; Luciani et al, 2013). Large tumors present several surgical challenges. The bulk of the mass can decrease working space and alter normal anatomic landmarks. This can result in disorientation with potentially higher risk of injury to surrounding structures. Continuous intraoperative reference to preoperative imaging as well as use of intraoperative ultrasonography is helpful. Flexible endoscopes may be used to better visualize portions of the surgical field that would otherwise not be visible via a conventional rigid laparoscope. The weight of large tumors may cause the surgeon to apply additional force for manipulation, potentially resulting in tumor rupture. It may be beneficial to use a hand port or additional trocars in these instances to allow for more widely distributed retraction of the kidney. Consideration may also be given to lymphadenectomy with larger, higher-stage tumors.

En Bloc Hilar Vessel Stapling

En bloc stapling of the renal hilum has been reported from several centers. An evaluation of 80 patients with mean follow-up of 35.2 months after either open radical nephrectomy or LRN, with routine use of en bloc hilar stapling, demonstrated no clinical evidence of arteriovenous fistula (White et al, 2007). Half of the patients also underwent CT arteriography at a minimum interval of 12 months postoperatively, and no patient had radiographic evidence of arteriovenous fistula. Another study evaluated patient outcomes in 433 patients undergoing LRN or nephroureterectomy, of whom 26 (6%)

underwent en bloc stapling only when hilar dissection was deemed difficult by the surgeon (Rapp et al, 2004). No cases of arteriovenous fistula were noted at a mean follow-up of 26 months. More recently, a randomized controlled trial of 70 patients undergoing either en bloc stapling of the renal hilum or separate ligation of the artery and vein reported no significant difference in postoperative blood pressure, heart rate, presence of bruit, or clinical or radiographic evidence of arteriovenous fistulization at 12 months' follow-up. Shorter operative times and lower estimated blood loss were noted in the en bloc ligation cohort (Chung et al, 2013). However, arteriovenous fistula may possibly occur as a more long-term complication after en bloc hilar stapling, and thus longer follow-up is needed to properly assess patients undergoing this form of hilar vascular management.

Port-Site Recurrence

Since the inception of laparoscopy and its application for surgical management of urologic malignancies, port-site seeding with recurrence has been of concern. In an international survey of 20 centers performing 2604 laparoscopic radical nephrectomies, no port-site seeding was reported (Micali et al, 2004). A review of all reported cases of port-site seeding in laparoscopy for urologic malignancy revealed a total of 28 cases. The majority involved aggressive upper tract transitional cell carcinoma, and 6 involved RCC (Eng et al, 2008). A more recent report of 133 laparoscopic radical nephrectomies demonstrated port-site metastases in 2 patients, both with higher pathologic stage with evidence of nodal metastases (Kumar et al, 2012). The cause of port-site recurrence is thought to be multifactorial and related to tumor aggressiveness, immune status of the patient, local wound factors, and surgical technique. The effects of pneumoperitoneum, aerosolization of tumor cells, insufflation gas type, and laparoscopic wound closure techniques have been studied by multiple authors and have been shown to be noncontributory (Ikramuddin et al, 1998; Tsivian et al, 2000; Gupta et al, 2002; Burns et al, 2005; Halpin et al, 2005; Jingli et al, 2006). As with open surgery, the most common cause is technical error and associated tumor spillage. Animal studies demonstrate that direct contact between tumor and port site enhances tumor growth (Bouvy et al, 1996), and hence the use of an impermeable specimen retrieval bag is recommended in all cases. Although the overall incidence of port-site metastasis is low—estimated at 0.09% to 0.18% (Rassweiler et al, 2003; Micali et al, 2004)—care should be taken in specimen handling and extraction to help minimize risk factors over which the surgeon has the most control.

Specimen Extraction

An area of controversy surrounding specimen extraction has been morcellation owing to the concerns for inadequate pathology assessment and staging, theoretic heightened risk of peritoneal or port-site seeding, bag rupture during morcellation, and overall recurrence. Although there is an advantage in terms of shorter incision length, there has been no benefit demonstrated in postoperative analgesic requirement (Hernandez et al, 2003). A multi-institutional study of the safety and efficacy of specimen morcellation in 188 patients with clinical stage T1 or T2 RCCs revealed 11 patients with recurrent disease (10 metastatic to lungs or viscera and 1 patient with port-site, renal fossa, and lymph node recurrence) (Wu et al, 2009). This demonstrates that mechanical morcellation may be safely performed in selected patients, although it is not considered standard of care. However, the ability to properly stage the patient remains in question, with studies demonstrating conflicting results. The feasibility of pathologic evaluation has been studied in comparative fashion by evaluating both fresh and formalin-fixed specimens before and after morcellation (Landman et al, 2000b). No alteration in determination of histology, grade, or local invasiveness of tumor was seen. Only specimen size could not be assessed after morcellation. A separate study of 23 morcellated specimens concluded that pathologic tumor stage in both renal cell and transitional cell carcinoma is severely limited by morcellation and must

rely partially on diagnostic imaging for lesion size, capsule, and renal vein involvement (Rabban et al, 2001). In addition, the incidence of pathologic stage T3a tumors was evaluated retrospectively in a series of 1781 patients and found to be 7.2% overall (Granberg et al, 2007). Imaging in the overwhelming majority of these patients did not predict stage pT3a disease. The authors concluded that without imaging that can more reliably predict fat invasion, accurate staging would be difficult if morcellation were performed.

If the specimen is to be morcellated, the surgeon should strictly adhere to proper technique including the use of a purpose-built sac, adequate draping, and change of gowns, gloves, and instruments after morcellation. The LapSac (Cook Urological, Spencer, IN) has been shown to be impermeable to bacteria and tumor cells, even after its use for morcellation (Urban et al, 1993). The sac is prepared by passing a moistened hydrophilic wire alternating through every third hole in the sac, which is then rolled from the bottom up and passed through a 12-mm trocar site. The trocar is replaced, leaving the wire and drawstrings outside the trocar. Graspers are used to place the specimen in the sac, which is held open by the wire, and the wire is removed (Wakabayashi et al, 2003). The drawstrings are grasped and brought through the periumbilical incision along with the neck of the sac, which is held tightly against the abdomen. Enlarging the trocar site by 1 cm will allow small amounts of tissue to protrude through the mouth of the sac. The morcellation process is performed with a ring forceps, working with alternating bites on the protruding tissue. Deep passes with the forceps should be avoided to prevent unintentional incorporation of bowel into the forceps. Pneumoperitoneum and direct laparoscopic visualization should also be maintained during the process to allow monitoring of the sac intracorporeally to avoid injury to structures resting against the sac or sac perforation.

Lymphadenectomy

Lymphadenectomy at the time of nephrectomy for presumed RCC, open or laparoscopic, remains controversial and is not commonly performed (Filson et al, 2012). It has been shown that presence of two or more adverse pathologic predictors (grade, sarcomatoid features, tumor size, stage, and necrosis) results in a higher likelihood of lymph node metastasis (Blute et al, 2004). In addition, patients with preoperatively or intraoperatively suspicious lymph nodes have been shown to have improved survival (median of 5-month benefit) when undergoing a lymph node dissection (LND) compared with those who did not (Pantuck et al, 2003). A retrospective study of 50 patients undergoing LRN alone versus 50 undergoing LRN with LND determined that 10% of the patients undergoing LND had positive nodes (Chapman et al, 2008). All patients were preoperatively node negative by cross-sectional imaging evaluation, and those with positive nodes all had high-grade lesions, stage T3 or T4. However, a randomized study comparing groups undergoing radical nephrectomy, with or without lymphadenectomy at the time of surgery, demonstrated no survival benefit of LND in patients with clinically negative lymph nodes (Blom et al, 2009).

It is clear that not every patient with RCC requires lymphadenectomy. However, a subset of patients with clinically suspicious lymph nodes, based on preoperative imaging criteria, preoperative biopsy pathology, intraoperative findings, or hereditary predisposition to aggressive pathology, may derive benefit from lymphadenectomy. Of note, there is no consensus on the extent of node dissection to be performed. The additional group that may benefit includes those with higher-stage tumors in the absence of suspicious lymph nodes, although survival data to support lymphadenectomy in this population are lacking.

Local Recurrence

The incidence of isolated local recurrence after nephrectomy with curative intent is approximately 1.8% (Itano et al, 2000; Margulis et al, 2009). Isolated local recurrence is defined as recurrence in the ipsilateral retroperitoneal lymph nodes, renal fossa, or adrenal gland without evidence of distant metastasis (Fig. 61-33). In a study

Figure 61-33. Renal fossa recurrence. (From Nóbrega de Jesus CM, Silva Casafus FA, et al. Surgical treatment of renal cell carcinoma recurrence at the renal fossa following radical nephrectomy. *Sao Paulo Med J* 2008;126:194–6.)

of 54 patients with isolated local recurrence managed with open surgical resection, median recurrence-free and cancer-specific survival rates of 11 and 61 months, respectively, were observed (Margulis et al, 2009). Perioperative systemic therapy with various combinations of immunotherapy, chemotherapy, and targeted tyrosine kinase inhibitors was used in 69% of cases. Given the rarity of these recurrences, published laparoscopic experience in surgically addressing them is quite limited to date. A series of 5 patients (1 open conversion for vena caval invasion) undergoing a hand-assisted approach to isolated local recurrence demonstrated that the procedure may be safely performed in selected patients (Bandi et al, 2008). At a mean follow-up of 43 months, cancer-specific and disease-free survival rates were 60% and 20%, respectively. The small number of patients in this report makes the results difficult to interpret. An open surgical resection can offer durable local control and cancer-specific survival in carefully selected patients; larger comparative laparoscopic series with sufficient follow-up are clearly needed to determine the efficacy of laparoscopy in these scenarios.

Renal Vein and Caval Tumor Thrombus

Several centers have now published their experiences with laparoscopy for renal cancers with associated tumor thrombus into the renal vein or inferior vena cava (Desai et al, 2003a; Hsu et al, 2003; Martin et al, 2008; Guzzo et al, 2009; Hoang et al, 2010; Bansal et al, 2014). After complete laparoscopic mobilization of the kidney and ligation of the renal artery, a laparoscopic DeBakey, vessel loop, or hand-assistance procedure is typically used to “milk” the tumor thrombus back toward the kidney. This allows either the endovascular stapler to be deployed on the renal vein excluding the thrombus, or a laparoscopic Satinsky clamp to be placed to isolate a cuff of the vena cava such that the cuff may be excised to allow intact specimen extraction without tumor at the margin. In cases in which a cuff of the inferior vena cava is excised en bloc with the renal vein stump, this cavotomy may then be oversewn using Prolene suture mirroring the open procedure. The use of intraoperative ultrasonography has also been described to aid in assessing the location of the extent of the tumor thrombus (Hsu et al, 2003). For higher thrombi, the cava is isolated as in open surgery and bulldog clamps or alternative methods are used to gain control during the cavotomy, extraction, and repair. To date, the approach has been largely limited to low- to mid-level caval thrombi, with reported results comparable with the open surgical experience.

Cytoreductive Nephrectomy

Patients with advanced RCC may require cytoreductive nephrectomy before the initiation of systemic secondary therapies. A comparative study of open versus laparoscopic cytoreductive nephrectomy in a selected group of patients with metastatic disease—but without local invasion, venous involvement, or bulky adenopathy—demonstrated similar 1-year survival between the two groups (61% vs. 65%) (Rabets et al, 2004). In addition, the laparoscopic group had less blood loss, shorter hospital stay, and shorter interval between surgery and the initiation of systemic therapy (36 vs. 61 days). Other studies have shown similar results (Eisenberg et al, 2006; Matin et al, 2006b; Blick et al, 2010), although the shorter interval to systemic therapy has not been consistently observed.

Surgical Salvage after Failed Ablative Therapies

Nephrectomy after ablation is technically challenging owing to resulting loss of tissue planes surrounding the lesion. A multi-institutional review of treatment outcomes for primary radiofrequency ablation (RFA) or cryotherapy revealed residual or recurrent disease in a median of 8.7% of patients (Matin et al, 2006a). Although a subgroup of these patients will undergo successful salvage ablative therapy, some may not be candidates for repeat ablation because of disease progression, tumor size, or failed repeat ablation. A report of 10 patients undergoing salvage surgery in this patient population showed that laparoscopic nephrectomy was only possible in 4 patients, and the remainder required either open partial or radical nephrectomy (Nguyen et al, 2008). Other studies have demonstrated laparoscopic salvage nephrectomy as feasible, but partial nephrectomy after ablation is often exceedingly challenging based on the literature (Kowalczyk et al, 2009; Breda et al, 2010). Extensive perinephric fibrosis was cited as the main factor complicating surgery in the postablation setting.

PARTIAL NEPHRECTOMY

The increased use of cross-sectional imaging has caused a downward stage migration and changed the paradigm for the typical presentation of kidney cancer. It has become the exception for kidney tumors to manifest with symptoms as had been the classic teaching for decades. **Kidney tumors are now most commonly diagnosed incidentally, at a small size and early stage, in asymptomatic healthy patients** (Jayson et al, 1998; Luciani et al, 2000; Leslie et al, 2003; Chow and Devesa, 2008). Although the majority of imaging-detected incidentally found renal lesions are benign simple cysts, one must be vigilant to not miss an early renal cancer. The prevalence of unsuspected, early-stage chronic kidney disease (CKD) underscores an important point: renal functional preservation and nephron-sparing strategies are important considerations when making management decisions in patients with a small renal mass (SRM) (Huang et al, 2006; Jeon et al, 2009). The desire to provide a minimally invasive alternative to treat patients with SRMs led to the application of laparoscopic techniques to nephron-sparing surgery (NSS).

Indications

The first transperitoneal LPN was reported in 1993 by Winfield and colleagues, with the retroperitoneal approach introduced 1 year later (Gill et al, 1994). Initially, LPN was applied to treat small clinical T1a exophytic renal masses (Fig. 61-34). With increasing experience, the indications of LPN have been expanded to include almost all patients with challenging tumor anatomy in complex clinical settings. The RENAL nephrometry score has in recent years become a popular method of characterizing the complexity of renal masses (Kutikov and Uzzo, 2009). Taking into account the (R) tumor diameter, (E) exophytic or endophytic character of the lesion, (N) nearness to the collecting system, (A) anterior or posterior location, and (L) location relative to the polar line, this system has

Figure 61-34. Computed tomography scan with intravenous contrast demonstrating a partially exophytic mid-pole clinical T1a lesion in the right kidney.

facilitated discussion of tumor complexity and series comparisons within the partial nephrectomy literature. Data have been conflicting regarding correlation of RENAL nephrometry score as a predictor of complications, but most evidence does suggest that increasing nephrometry score is associated with complication risk in minimally invasive approaches for management of the SRM (Mayer et al, 2012; Okhunov et al, 2012; Ellison et al, 2013; Schmit et al, 2013; Tanagho et al, 2013).

Clinical Stage T1b and Greater Tumors

LPN was initially restricted to patients with tumors 4 cm or smaller and clinically staged as T1a. Technical advances in laparoscopic techniques, along with demonstration of equivalent results to open surgery for T1a tumors, provided the groundwork for approaching larger lesions (Leibovich et al, 2004; Dash et al, 2006; Mitchell et al, 2006; Rais-Bahrami et al, 2008; Gupta et al, 2013). Simmons and colleagues (2009a) reported perioperative outcomes of LPN in 58 patients for T1b tumors. Mean tumor size was 6 cm, and 55% of tumors were centrally located. Although patients with pT1b tumors more often underwent pelvicalyceal repair ($P = .004$) and heminephrectomy ($P < .001$), they had similar operative time, blood loss, and hospital stay but longer warm ischemia time than patients with tumors smaller than 4 cm. Tumor size greater than 4 cm did not increase risk for positive cancer margins, intraoperative complications, or postoperative urologic complications. Of note, in patients with tumors smaller than 2 cm, 2 to 4 cm, and 4 to 7 cm (stage \geq III), CKD existed preoperatively in 31%, 35%, and 44% of patients, respectively, and postoperatively in 52%, 53%, and 63%, respectively ($P =$ nonsignificant). Also, other reports of LPN for cT1b tumors have corroborated the renal functional benefits compared with radical nephrectomy, even in the setting of a normal contralateral kidney (Simmons et al, 2009b; Deklaj et al, 2010). This underscores the importance of attempting a nephron-sparing approach in all patients when feasible. Given adequate laparoscopic experience and appropriate patient selection, the perioperative outcomes of LPN for clinical T1b tumors appear comparable to those achieved for clinical T1a tumors.

Recently, Lane and colleagues (2013) evaluated long-term oncologic outcomes of LPN compared with open partial nephrectomy (OPN) for clinical stage T1 tumors. Combining cases of cT1a and cT1b tumors, their study investigating follow-up on 1541 patients demonstrated that the operative approach (laparoscopic vs. open) was not an independent predictor of metastasis ($P = .42$) or all-cause mortality ($P = .13$). Also, the median decrease in glomerular filtration rate was not significantly different comparing those who underwent LPN versus OPN ($P = .50$).

Laparoscopic Heminephrectomy

Finelli and colleagues (2005) compared outcomes of laparoscopic heminephrectomy (excising greater than 30% of renal parenchyma) in 41 patients, with a contemporary group of 41 consecutive patients who underwent LPN with less than 30% resection. Except for a longer ischemia time (39 vs. 33 minutes) in the heminephrectomy cohort, there were no differences between the two groups regarding blood loss, operating room time, analgesic requirement, hospital stay, postoperative serum creatinine, and overall complications. All surgical margins were negative. A similar report evaluating 24 patients who underwent laparoscopic heminephrectomy with other LPN done at the same institution over the same time period showed comparable results (Sobey et al, 2012). The indications for the cases of laparoscopic heminephrectomy in this study were larger tumors with higher nephrometry scores. Operative times and warm ischemia times were significantly higher in the cohort of patients undergoing heminephrectomy, but estimated blood loss, length of hospitalization, complications, and change in renal function were equivalent.

Specific technical considerations inherent to laparoscopic heminephrectomy include routinely performing deeper renal parenchymal resections, transection of sizable intraparenchymal blood vessels, and intentional entry into the pelvicalyceal system (PCS). The primary goals of laparoscopic heminephrectomy and LPN are the same: achieve negative surgical margins, perform clipping or suture repair to secure renal vessels, and, where necessary, repair the collecting system while minimizing ischemia time.

Central and Hilar Tumors

Central tumors are defined as those abutting or invading the central renal sinus fat and/or the collecting system on preoperative imaging. These tumors deeply infiltrate the renal parenchyma, and their excision requires intentional entry into and potentially suture-repair of the PCS along with complex parenchymal reconstruction, all within the time constraints of renal ischemia. The technical complexity of such cases depends on the location of the individual tumor and the type of suturing angles available for laparoscopic instruments in the dominant and nondominant hands. Frank and colleagues (2006) compared experience with LPN for 154 central tumors with LPN for 209 peripheral tumors. Although blood loss was similar, central tumors were associated with somewhat longer operative time, ischemia time, and hospital stay, and more early postoperative complications. There was only one positive margin for cancer in each group. In series of completely intraparenchymal tumors, Chung and colleagues (2011) compared these cases with three other tumor groups—completely exophytic tumors, tumors infiltrating up to sinus fat, and tumors infiltrating but not up to sinus fat—and found that there was no statistically significant difference among the groups in rate of complications, positive margins, operative blood loss, or tumor excision or warm ischemia times.

Hilar tumors, defined as tumors located in the renal hilum in direct contact with the renal artery and/or vein on cross-sectional imaging, were initially considered to be a contraindication to LPN, but with increased experience these challenging tumors have been successfully managed with LPN by several groups. In 2005, an initial experience with LPN outcomes for hilar tumors in 25 patients was reported (Gill et al, 2005). Mean tumor size was 3.7 cm (range 1 to 10.3). LPN was successful in all cases, without any open conversions or operative reinterventions. Postoperative hemorrhage occurred in 3 early patients. Preoperative 3D video reconstruction of triphasic spiral CT was important in detailing the number, inter-relationship, anatomic course, and position of the renal vessels in relation to the tumor. George and colleagues (2014) reported their experience with 43 LPNs for hilar tumors compared with a contemporary series of 445 LPNs for nonhilar tumors, finding no significant difference in any perioperative parameter investigated including warm ischemia time and postoperative renal functional outcomes at 6 months' follow-up.

Tumor in a Solitary Kidney

Partial nephrectomy for tumor in a solitary kidney is challenging, whether performed via the open or the laparoscopic approach. The margin for error is small because a complication could result in temporary dialysis, or worse, render the patient anephric. A multi-institutional analysis by [Hillyer and colleagues \(2013\)](#) reported on 26 patients undergoing robotic-assisted laparoscopic partial nephrectomy (RaLPN) for a tumor in a solitary kidney; the majority (62%) rendered solitary from prior surgery for renal malignancy. No cases were converted to open surgery, median warm ischemia time was 17 minutes, and at a median 6-month follow-up the estimated glomerular filtration rate (eGFR) was not significantly affected. Prior report of 22 patients undergoing conventional LPN in a solitary kidney at a single institution reported mean warm ischemia time of 29 minutes, two procedures (9%) electively converted to open surgery, and one kidney lost because of delayed postoperative hemorrhage ([Gill et al, 2006](#)). Authors of both studies concluded that minimally invasive partial nephrectomy for management of tumors in a solitary kidney was feasible and offered reliable preservation of renal function.

Management of Multiple Tumors

NSS is increasingly considered the preferred treatment for patients with multiple, ipsilateral tumors owing to the potential for contralateral involvement or recurrence. LPN has been applied in this clinical setting as well. [Abreu and colleagues \(2013\)](#) published their experience of 33 patients who underwent LPN, with or without robotic assistance, for multiple ipsilateral renal tumors matched with 33 patients treated for a single renal tumor. Perioperative results demonstrated significantly longer operative times and length of hospitalization, with no significant difference in warm ischemia times, blood loss, rate of transfusion, or conversion to radical nephrectomy.

Other Indications

LPN has also been performed in the following unique clinical settings: adrenal involvement from an upper pole tumor requiring excision with concomitant adrenalectomy ([Ramani et al, 2003](#)); repair of concomitant renal artery disease ([Steinberg et al, 2003](#)); tumors in congenitally anomalous kidney, such as horseshoe kidney ([Tsivian et al, 2007](#)); in obese patients ([Romero et al, 2008](#)); after prior ipsilateral renal surgery ([Turna et al, 2008](#); [Boris et al, 2013](#)); and in the setting of hereditary kidney cancer syndromes ([Rogers et al, 2008](#)). Although each of these unique settings poses different challenges, the use of LPN in any clinical setting should realistically be able to achieve the central goals of safely removing the malignant tumor while sparing normal renal parenchyma, minimizing ischemia and operative times, and minimizing postoperative complications.

Procedure

Technical Issues

The principal technical challenge during LPN stems from the complexity of laparoscopic tumor excision and sutured renal reconstruction in a time-sensitive manner. The primary objectives are to complete tumor excision with negative margins, achieve hemostasis, and minimize warm ischemia time. Successful LPN for complex tumors requires an in-depth understanding of 3D renal anatomy, real-time intraoperative appreciation of visual cues, and precise, efficient intracorporeal suturing.

Transperitoneal Laparoscopic Partial Nephrectomy

The transperitoneal approach offers many features that are crucial for performance of advanced LPN: larger working space, more familiar landmarks, greater versatility of instrument angles, and technical ease of suturing. The initial portion of the procedure is

performed as previously described for transperitoneal access to the kidney.

Retroperitoneal Laparoscopic Partial Nephrectomy

Although most LPN surgeons prefer the transperitoneal approach for almost all renal tumors, some use the retroperitoneal approach, which has advantages for select posteriorly located upper pole apical tumors. After entry into the retroperitoneum and establishment of a working space as previously described, the kidney may be lifted anteriorly off the psoas muscle to allow visualization of the arterial pulsation. The dissection of the renal hilum can then proceed to facilitate bulldog clamp placement when deemed necessary. In a comparison of 32 retroperitoneal with 19 transperitoneal LPNs, choice of approach was based on tumor location ([Wright and Porter, 2005](#)). The retroperitoneal approach was associated with shorter operating time, decreased blood loss, more rapid return of bowel function, and shorter hospitalization. A comparison of 100 transperitoneal with 63 retroperitoneal LPNs demonstrated that blood loss, perioperative complications, postoperative serum creatinine, analgesic requirements, and histologic outcomes were comparable in the two groups ([Ng et al, 2005](#)). Accordingly, the choice of a transperitoneal or retroperitoneal LPN approach is dictated primarily by surgeon experience and tumor location. Other factors that may influence the decision include tumor size, number of tumors, number of arteries supplying the kidney, amount of visceral fat surrounding the kidney, and route of any prior open surgery on the quadrant of interest.

Robotic-Assisted Laparoscopic Partial Nephrectomy

RaLPN has been used by several centers as an extension of conventional LPN, reducing difficulty of fine intracorporeal tissue manipulation including tumor resection and renorrhaphy. This has broadened the cohort of urologic surgeons able to offer a minimally invasive approach to partial nephrectomy to include those surgeons without advanced laparoscopic skills ([Gettman et al, 2004](#); [Caruso et al, 2006](#); [Kaul et al, 2007](#); [Rogers et al, 2008](#)). Many surgeons with advanced laparoscopic skills also use robotic assistance to facilitate skeletonization of renal arterial branches when selective clamping is to be used. Potential differences in cost aside, the addition of robotic assistance to LPN is considered to be comparable to conventional LPN. Randomized trials comparing the two modalities are lacking.

The beginning of the case is often conducted with conventional laparoscopy to varying degrees, sometimes to the point of tumor resection when the robotic platform is docked. Others use the robotic assistance throughout the case, starting immediately after trocar insertion.

The responsibilities of the bedside assistant often include aiding in clamping the renal hilum, providing suction and retraction to maintain a clean operative field, delivery and cutting of sutures, and clip placement as needed. Newer robotic instrumentation has allowed the surgeon at the console to perform many of these maneuvers, but additional exchanges of robotic instruments are necessary. The surgeon at the console also performs tumor excision, hemostatic suturing, and pelvicalyceal and parenchymal suture reconstruction. On completion of renal reconstruction, the hilum is unclamped, and additional parenchymal sutures are placed, as needed, to ensure hemostasis. The robot is undocked and laparoscopic exit completed.

Tumor Localization and Excision

Regardless of the approach (transperitoneal LPN, retroperitoneal LPN, or RaLPN) the techniques of tumor localization and excision are essentially identical. Once the initial dissection is complete, including isolation of the hilar vessels, intraoperative ultrasonography is used to confirm location, width, and depth of the tumor ([Fig. 61-35](#)). Ultrasonography may also be used to confirm absence of additional lesions in the kidney. The Gerota fascia is entered away from the lesion to expose the renal capsule. Using the monopolar

Figure 61-35. Intraoperative ultrasonography is used to confirm location, width, and depth of the tumor.

Figure 61-37. Once the margin around the tumor has been scored, the hilum is clamped en bloc using a laparoscopic Satinsky clamp, or the artery and vein are clamped separately using bulldog clamps.

Figure 61-36. After the Gerota fascia is cleared to expose the lesion and the renal capsule, with use of monopolar scissors or hook cautery, the capsule is scored circumferentially around the tumor.

scissors, the capsule is scored circumferentially around the tumor (Fig. 61-36), and the hilum is classically then clamped using laparoscopic bulldog clamps (Fig. 61-37). The scored line may then be incised using cold shears (Fig. 61-38), and with the assistance of a suction-irrigator device to provide both countertraction and a clear operative field, the tumor excision is completed. In some patients, adherent fat not easily dissecting off the renal capsule will necessitate a subcapsular dissection to visually identify the borders of the tumor before resection.

Hemostasis

The most widely used technique to achieve hemostasis of the partial nephrectomy bed is suture renorrhaphy. Suturing techniques range from suturing the base with or without adjunctive

Figure 61-38. The scored margin around the tumor is incised using cold shears with the renal hilum clamped. The suction-irrigator both provides countertraction and helps to maintain a clear operative field and adequate margin of normal renal tissue.

biologic hemostatic or sealing agents, or a Surgicel bolster (Johnson and Johnson, New Brunswick, NJ), to using only a horizontal mattress suture to close the capsular and parenchymal defect (Fig. 61-39). During extrication, surgical clips may be used to ligate any visualized vessels while coming across the surface of the parenchyma. A number of tissue sealants are available and used based on surgeon preference: gelatin matrix thrombin sealant (FloSeal; Baxter, Deerfield, IL), fibrin glue (Tisseel; Baxter), fibrin sealant (Evicel; Ethicon), polyethylene glycol hydrogel (Coseal; Baxter), cyanoacrylate glue (Dermabond; Ethicon), BioGlue (CryoLife; Atlanta, GA), and homemade versions of similar matrix materials immersed in hemostatic solutions. Of note, no study published to date has clearly demonstrated the true benefit of the use of any of these agents.

Figure 61-39. A, After use of the argon beam coagulator on the exposed parenchyma, interrupted absorbable sutures are placed for the renorrhaphy. The collecting system has already been repaired and the suction-irrigator serves to provide countertraction and maintain a clear operative field. B, The sutures may be laparoscopically tied with optional pledgets to help prevent capsular tearing during closure. C, Alternatively, sutures with preplaced Lapra-Ty clips (Ethicon, Cincinnati, OH) at the tail are used and secured with an additional Lapra-Ty clip after the needle is passed and tension on the closure is adjusted.

During LPN for selected small, superficial, exophytic tumors, various thermal (radiofrequency, microwave, ultrasonic) and novel alternative (laser, water-jet) energy sources have been used for hemostasis clinically and in the laboratory (Lotan et al, 2004; Herrell and Levin, 2005; Moinzadeh et al, 2005; Hindley et al, 2006; Liu et al, 2006; Thomas et al, 2013).

Collecting System Repair

Central tumors abutting the renal sinus fat and collecting system may require deliberate entry into the PCS to ensure negative surgical margins during tumor excision. For this reason, PCS entry is a common occurrence in contemporary LPN practice. Prospective comparison of perioperative outcomes in 27 LPNs with

pelvicalyceal entry with 37 LPNs with no pelvicalyceal entry (Desai et al, 2003b) revealed similar operating room time, tumor excision time, and blood loss. However, PCS suture repair was associated with longer warm ischemia time and hospital stay. None of the patients undergoing PCS suture repair developed a urinary leak. The results of this early study showed that intentional entry into the PCS for central tumors could be safely and effectively repaired (Fig. 61-40). Zorn and colleagues (2007) also reported that cases with PCS repair compared with those not requiring PCS repair demonstrated longer operative times and warm ischemia times, without significant differences in intraoperative or postoperative complications including urine leak and need for transfusion. Suture repair of the PCS with running 3-0 or 4-0 polyglactin can be used. Alternatively, one may close the renal parenchyma and capsule over the

Figure 61-40. A, When deep resection is required, the collecting system will often be transected. With occlusion of the renal vessels, these defects can easily be identified and closed using absorbable sutures. The cut edge of the collecting system is identified with the tip of the needle and elevated. B, An interrupted figure-of-eight suture or running suture is used to completely close the collecting system. The integrity of the repair can be determined by intravenous indigo carmine administration or retrograde instillation, if a ureteral catheter was placed at the beginning of the case. Care must be taken not to destroy the suture, if argon beam coagulation of the parenchyma surface will be performed.

defect without primary PCS repair. In either case, a drain should be placed to reduce the risk of perinephric urinoma. No randomized studies of closure versus nonclosure of the collecting system exist to show the necessity of repairing the PCS.

Renal Hypothermia

Multiple techniques have been described for laparoscopic renal hypothermia: surface cooling with ice slush, instillation of cold saline through a retrograde ureteral catheter, and intra-arterial perfusion of cold isotonic solution (Marley et al, 2011; Abe et al, 2012; Saitz et al, 2013). Although all of these techniques are clinically feasible and reasonably effective, they are rarely used in routine practice. This is not only because of their complexity, but also because the majority of tumors subjected to LPN do not require an inordinately long period of warm ischemia for resection and reconstruction. Greater consideration of hypothermic techniques may be given in settings of a solitary kidney or significant renal insufficiency, depending on surgeon preference, tumor complexity, and expected ischemia time (if any).

Warm Ischemia and Hilar Control

The limit of safe renal warm ischemia time has historically been considered to be 30 minutes. Although supported by canine and anecdotal clinical data, no scientifically rigorous clinical study has defined an ischemic dose-response curve to date. Indeed, data exist suggesting that up to 90 minutes may be reasonable (Orvieto et al, 2005). The difficulty in understanding the effects of surgical renal ischemia is related to insufficient data and many confounding variables affecting global renal function. While this issue is being debated, efforts should be made to minimize warm ischemia time to the greatest extent possible.

From a technical standpoint, hilar control can be achieved by using bulldog clamps individually on the renal vessels, the renal

artery alone without clamping the vein, or a laparoscopic Satinsky clamp for en bloc hilar clamping. Several techniques have also been investigated in an effort to reduce renal ischemia and further minimize any loss of renal function that might occur as a result of NSS.

Traditionally during LPN, the entire tumor excision and renal repair are performed in the ischemic kidney, with the hilar vessels clamped. Early unclamping is a modification of the traditional technique with the primary goal of decreasing warm ischemia time (Nguyen and Gill, 2008). In this technique, the renal hilum is clamped only up to placement of the initial, central, running suture in the resection bed. Results suggest that this technique does indeed reduce warm ischemia time with comparable estimated blood loss and transfusion rates relative to conventional hilar clamping (Peyronnet et al, 2014).

Off-Clamp Laparoscopic Partial Nephrectomy Technique. Select tumors can be excised during LPN without hilar clamping. Typically, tumors best suited for this technique are more superficial, exophytic, noninfiltrating lesions. In 2003, Guillonnet and colleagues compared LPN with ($n = 12$) and without ($n = 16$) hilar clamping using ultrasonic shears and bipolar cautery, concluding that hilar clamping provided decreased blood loss, shorter operating time, and superior surgical performance. A recent study compared 150 off-clamp LPNs with 289 traditional clamped LPNs (George et al, 2013). Significant differences ($P < .05$) in the off-clamp group relative to the on-clamp group included smaller, more relatively exophytic tumors. The group of off-clamp cases had significantly larger estimated blood loss (338.4 mL vs. 276.8 mL, $P = .023$) and less decrease in eGFR at 6-month follow-up (-3.9 vs. -11.7 , $P = .035$) with no difference in operative time, length of hospitalization, positive margins, or transfusions. As experience improves, an increasing number of procedures may be performed off-clamp to optimize renal perfusion and potentially renal functional outcomes. Several groups have demonstrated the feasibility and safety of various iterations of performing off-clamp LPN, including its use for treatment of more challenging lesions (Novak

et al, 2012; Kaczmarek et al, 2013; Salami et al, 2014). Tumors that are larger, deeper, central, or hilar may require more substantial dissection and reconstruction, but may also be safely excised off-clamp with adequate experience. Several of these experiences have been reviewed, with overall support of the safety of the approach with potential renal functional benefits (Simone et al, 2013; Liu et al, 2014b).

Selective Renal Arterial Clamping. Extensive hilar dissection beyond that traditionally performed for main renal artery clamping can provide the surgeon with the option of selectively clamping a single or multiple arterial branches supplying the area of the tumor without causing ischemia to the renal remnant. This technique has the theoretic advantage of providing a relatively bloodless field for tumor resection, without compromising blood flow to the entire kidney. Studies have demonstrated longer operative times and higher perioperative transfusion rates relative to main artery clamping (Desai et al, 2014). Near-infrared fluorescence imaging has been used in conjunction with selective arterial clamping to confirm ischemia to the desired area of the kidney (Borofsky et al, 2013).

Renal Artery-Only versus Artery-Plus-Vein Clamping. It is theorized that artery-only clamping during partial nephrectomy would allow retrograde venous blood flow with potentially partial oxygenation to the renal parenchyma. In a solitary kidney pig model, Orvieto and associates (2007) found that artery-only clamping resulted in lower serum creatinine rises during postoperative days 1 to 3 than in animals that underwent complete hilar occlusion. It is interesting to note that this effect was not observed in animals that underwent laparoscopic surgery. It was concluded that artery-only clamping provided immediate postoperative benefit, and that this benefit was likely offset by pneumoperitoneum-induced venous compression during laparoscopy. In contrast, the same group found a benefit to artery-only clamping in a case-control study of patients undergoing LPN with artery-only clamping ($n = 25$) versus simultaneous clamping of the artery and vein ($n = 53$) (Gong et al, 2008). A significant decrease in serum creatinine and creatinine clearance was observed in patients undergoing simultaneous clamping of the artery and vein compared with preoperative levels. This effect was not observed in those undergoing artery-only clamping. In addition, there were no statistically significant differences observed in either blood loss or positive margin rate between the groups.

Parenchymal Compression and Clamping versus Vascular Clamping. Similar in concept to selective arterial clamping, manual compression or clamping of the kidney during tumor excision and renorrhaphy can theoretically allow continued perfusion of the renal remnant while providing ischemia to the area of parenchyma containing the tumor and a bloodless operative field. The time-sensitivity of tumor excision and renorrhaphy is also reduced. Manual compression can be effective for small exophytic tumors, although the renal vasculature should always be accessible to allow emergent clamping in the case of hemorrhage. Issues to consider include the possibility of tissue trauma caused by excessive compression, and the limitation of this approach to peripheral tumors during open and hand-assisted laparoscopic procedures only. Manual compression techniques would not be feasible in partial nephrectomy of central, hilar, or large tumors, or for pure laparoscopic surgery without specialized instrumentation. Several authors have published their initial experiences in a small number of patients using techniques of parenchymal clamping in selected patients with peripheral renal cortical tumors (Verhoest et al, 2007; Simon et al, 2009). All patients in these studies had negative surgical margins, and no changes in renal function were reported. The primary limitation of the technique is that only selected patients with peripherally located tumors are candidates.

Laparoscopic Partial Nephrectomy: Contemporary Outcomes

It is important to consider comparisons of LPN patients with patients who have undergone radical nephrectomy or OPN to

effectively gauge outcomes. Oncologic outcomes, perioperative complications, renal functional outcomes, and overall survival are all critical metrics in determining the safety and efficacy of the techniques.

Series comparing radical versus partial nephrectomy for T1 solitary lesions suggest that a nephron-sparing approach is as effective as radical nephrectomy for cancer treatment over the long term (Lau et al, 2000; Lee et al, 2000; Thompson et al, 2009). Retrospective studies have also suggested that patients undergoing partial nephrectomy may experience improved overall survival relative to patients undergoing radical nephrectomy (Thompson et al, 2008), possibly secondary to reduced rates of renal insufficiency and cardiovascular morbidity and mortality (Huang et al, 2006). More recently, the only randomized trial comparing radical versus partial nephrectomy for the treatment of renal tumors smaller than 5 cm failed to demonstrate an overall survival benefit for patients undergoing partial nephrectomy (Van Poppel et al, 2011). The group undergoing partial nephrectomy was seen to have higher risk of cardiovascular death, although the explanation for this finding is unclear and the authors acknowledge that the study was not designed to evaluate differences in cardiovascular outcomes. Although this result certainly should prompt additional investigation, the authors acknowledge that their findings contradict those of prior retrospective analyses and they continue to encourage a minimally invasive nephron-sparing approach when possible.

An 1800-patient retrospective multi-institutional study compared a mature series of 1029 OPN cases with the initial LPN cases for solitary T1 tumors 7 cm or smaller (Gill et al, 2007). Tumors in the OPN group were larger (3.3 vs. 2.6 cm), and more often located centrally (53% vs. 34%) or in a solitary kidney ($P < .001$ for all comparisons). LPN had less blood loss and shorter operative time, hospital stay, and convalescence ($P < .001$ for all comparisons). Overall postoperative complications (25% vs. 19%) and conversion to radical nephrectomy (1% vs. 0%) were somewhat greater in the LPN group. It is important to note that LPN and OPN were similar with regard to intraoperative complications (1.8% vs. 1%), positive surgical margins for cancer (1.6% vs. 1%), 3-year oncologic outcomes, and 3-year renal functional outcomes. However, LPN had a 10-minute longer ischemia time (30 vs. 20 minutes), and somewhat higher postoperative hemorrhage (4.2% vs. 2%) and reintervention rate.

With increasing LPN experience and more common use of techniques to reduce warm ischemia time (early unclamping, off-clamp partial nephrectomy, selective arterial clamping, and parenchymal clamping), contemporary LPN outcomes have improved significantly. Specifically, the two remaining concerns for higher postoperative hemorrhage and longer ischemia time with LPN have now been addressed, leading to significantly decreased ischemia time and reduced occurrence of postoperative hemorrhage. **Surgical experience and improvements in instrumentation have allowed continued progress in reducing warm ischemia time, perioperative complications, and renal functional outcomes even with increasing complexity of tumors being addressed with LPN** (Gill et al, 2011; George et al, 2013; Salami et al, 2014). **Outcomes of LPN parallel those of OPN while reducing perioperative morbidity.**

Positive Surgical Margins

The clinical significance of a pathologic positive surgical margin after partial nephrectomy, whether laparoscopic or open, has prompted several studies evaluating outcomes specifically in these patients. In a group of 1344 patients undergoing OPN, positive surgical margins were noted in 77 (5.5%) (Yossefowitch et al, 2008). The 10-year probability of freedom from local recurrence and progression to metastatic disease was 93% for both. There were no significant differences noted between those with positive and negative margins. Several laparoscopic surgeons have reported similar results with positive margin rates ranging from 1% to 1.8% with no increased risk of local recurrence or metastasis (Permpongkosol et al, 2006a; Lane et al, 2013). A recent multi-institutional report found contradictory results in the 2.2% of 943 patients who underwent RaLPN with positive margins on final pathology; the

hazard ratio (HR) of recurrence and metastasis was 18.4 relative to those with negative margins (Khalifeh et al, 2013). Although these data demonstrate that many patients with pathologically positive margins may be observed, negative surgical margins should always be the goal in any oncologic procedure.

Long-Term Outcomes

Long-term data on LPN are now available (Table 61-4), and appear similar to those for OPN. Five-year cancer-specific survival after LPN has been reported up to 100% (Lane et al, 2007). Most recently, a comparative study of 10-year outcomes compared 625 patients undergoing LPN with 916 patients undergoing OPN for single clinical stage T1 (≤ 7 cm) tumors from 1999 to 2007 (Lane et al, 2013). There were statistically significant differences in the LPN and OPN cohorts noted, including preoperative renal function (eGFR 82 vs. 74 mL/min/1.73 m²), smaller radiographic tumor size (2.6 vs. 3.5 cm), and absolute indication for partial nephrectomy. Pathologic features were also noted to be different between the LPN and OPN groups, including smaller tumor size (2.5 vs. 3 cm), larger percentage of benign lesions (26% vs. 19%), and fewer pT1b lesions (14% vs. 33%). Patients with pathologically confirmed RCC had comparable 5-year recurrence-free survival in both the pT1a (97.8% vs. 97.1%) and pT1b (93.1% vs. 92.7%) subgroups. A total of 45 patients undergoing LPN and 254 patients undergoing OPN had 10-year follow-up with 78% and 72% overall survival, respectively. The recurrence rate in the OPN cohort was higher relative to LPN; however, this is likely a reflection of the inherent differences between the cohorts noted earlier. On multivariable analysis, predictors of metastasis included larger tumor size, absolute indication, and comorbidity, but not LPN (HR 0.72; confidence interval [CI] 0.36 to 1.34; $P = .32$). The authors concluded that LPN and OPN provide similarly excellent long-term overall survival, with the vast majority of patients experiencing metastasis-free survival.

In experienced hands, LPN is equivalent to OPN, with shorter ischemia times, equivalent complication rates, and comparable renal functional outcomes. As a result, large-volume centers routinely offer LPN for the majority of renal tumors. These include technically challenging SRMs, including tumors that are hilar, central, completely intrarenal, larger (4 to 7 cm, pT1b), or located in a solitary kidney (Leslie et al, 2013).

LAPAROSCOPIC ABLATIVE TECHNIQUES

As the incidence of the SRM has increased with the prevalence of cross-sectional imaging, a stage migration has occurred such that a rising number of patients have incidentally been found to have low-stage disease. Cancer-specific survival rates in excess of 95% (Frank et al, 2005; Lane et al, 2007) with cryoablation and RFA have given credence to use of ablation as an alternative treatment. High-intensity focused ultrasonography, microwave therapy, and high-intensity focused radiation have also been investigated. The primary goals of these ablative techniques are complete tumor destruction with minimization of morbidity. The potential advantages include less blood loss, decreased need for dissection, and fewer complications. Indications are similar for all the ablative technologies and include lesions in patients with significant comorbidities, solitary kidneys, and hereditary RCC. The percutaneous approach is preferred for treatment of SRMs owing to its lower morbidity, but in some instances it may not be possible because of tumor location or proximity to adjacent organs. For these reasons, laparoscopy is required for direct visualization and manipulation to make treatment delivery feasible and safe. Because cryoablation and RFA are the most prevalent in clinical applications, these ablative techniques are discussed here in further detail.

Cryoablation

Laparoscopic cryoablation may be delivered using either a transperitoneal or retroperitoneal approach, with the decision resting

primarily on tumor location. The kidney is mobilized and the Gerota fascia is opened in a manner similar to that used for LPN. The fat overlying the tumor may be excised and placed in a specimen bag for extraction and pathologic analysis. Biopsy samples of the tumor itself may also be taken with a 14- or 18-gauge biopsy needle for histopathologic diagnosis. Placement of the cryoablation probes into the tumor can be performed percutaneously, leaving the laparoscopic ports free for instrumentation and tissue manipulation. Direct visualization of probe placement and depth of placement are confirmed with laparoscope and intraoperative ultrasonography, respectively. Number and spacing of probes are dictated by probe-specific ablative shape and diameter, and they should be positioned to ensure cryolesion overlap, typically parallel to one another in a triangular or quadrangular configuration. The tip of the probes should be advanced just beyond the deepest margin of the tumor.

The progress of the iceball formation may be monitored in real time using intraoperative ultrasonography, and the iceball should extend approximately 1 cm beyond the edge of the tumor. Keeping in mind that the progress of the iceball cannot be abruptly stopped, caution should be exercised to avoid contact of the iceball with the renal collecting system, ureter, renal vasculature, or adjacent organs. After the freeze-thaw cycles are complete, the probes are removed with a gentle twisting motion. If any bleeding occurs, it can usually be controlled by applying pressure or, if necessary, hemostatic agents such as fibrin glue or Floseal.

Radiofrequency Ablation

Similar to cryoablation, RFA may be administered laparoscopically using either a transperitoneal or a retroperitoneal approach. After ultrasound confirmation of tumor location and size and biopsy of the overlying fat and tumor tissue, as with cryoablation, the RFA probe is introduced into the tumor, and the tines are deployed to a diameter that ensures ablation of the tumor and a 1-cm margin of normal renal tissue. The size of the thermal lesion is determined by temperature- or impedance-based monitoring. The probe uses an alternating current of high-frequency radio waves, causing ion vibration. The resistance in the tissue causes generation of sufficient heat to result in thermal tissue damage—tumor coagulation, protein denaturation, and cell membrane disintegration all occur (Goldberg et al, 2000; Aron and Gill, 2007). Immediate histopathology after RFA shows hypereosinophilia and pyknosis, which is subsequently replaced by coagulative necrosis within days to weeks (Crowley et al, 2001). For achievement of these effects, optimal temperatures for ablation range from 60° C to 100° C and avoid tissue vaporization, which may occur at temperatures over 105° C (Goldberg et al, 2000; Crowley et al, 2001).

Unfortunately, unlike with cryoablation, real-time ultrasonography cannot be used to monitor the thermal lesion induced by RFA. RFA itself may interfere with ultrasound imaging, and the affected tissue does not have any immediate change in echotexture. Color Doppler ultrasonography has been evaluated during RFA but does not reliably contribute to monitoring the lesion (Crowley et al, 2001). Although MRI, allowing for real-time thermometry, has been used to monitor the changing appearance of ablated lesions at the time of percutaneous treatment (Lewin et al, 2004), there is no current imaging technique that effectively monitors the progress of RFA lesions intraoperatively. Questions have been raised about temperature-based monitoring of the lesion owing to the observation that temperatures measured at the limit of the ablated area are actually 20° C to 30° C cooler than what is measured by the probe thermocouples. A potential solution involves the use of independent temperature probes to monitor temperature at the edge of the desired treatment area (Wingo et al, 2008). This allows a more definitive end point in the ablation cycle. Alternatively, an impedance-based system may be used. Instead of direct temperature measurement, this method relies on tissue impedance; sufficiently desiccated tissue becomes an insulator, and at an impedance level of 200 Ω , further progression of the thermal lesion is unlikely to occur (Lewin et al, 1998).

Treatment Outcomes

Several studies have reported promising oncologic outcomes of laparoscopic cryoablation (Cestari et al, 2004; Weld et al, 2007; Malcolm et al, 2009). A study of 62 patients undergoing laparoscopic cryoablation, with a median tumor size of 2.52 cm and mean follow-up of 76 months, demonstrated a 6-year Kaplan-Meier estimated disease-free survival of 80%, cancer-specific survival of 100%, and overall survival of 76.2% among patients with biopsy proof of RCC (Tanagho et al, 2012).

A comparison of 145 patients undergoing laparoscopic cryoablation with 118 patients undergoing percutaneous cryoablation demonstrated equivalent oncologic control as measured by recurrence-free survival and overall survival with a mean follow-up of 71.4 and 38.6 months for the two groups, respectively (Kim et al, 2014).

A recent systematic review and meta-analysis comparing laparoscopic cryoablation with LPN and RaLPN found significantly shorter operative times, lower estimated blood loss, shorter length of stay, and a lower risk of complications; however, there was an increased risk of local and metastatic tumor progression, prompting the authors to conclude that cancer control should be balanced with the risk of perioperative complications in proper patient counseling and selection (Klatte et al, 2014).

A multi-institutional study of RFA and cryoablation outcomes in 616 patients demonstrated residual or recurrent disease in 13.4% of patients undergoing RFA and 3.9% of patients undergoing cryoablation (Matin et al, 2006a). Overall, primary therapy failed in 8.7% of patients, and after salvage ablative therapy the failure rate was reduced to 4.2%. The authors noted that the majority of failures were detected after less than 3 months, and that cross-sectional imaging should be obtained three or four times at spaced intervals for the first year after treatment. A subsequent meta-analysis of patients undergoing partial nephrectomy, ablative therapies, or observation noted a higher risk of recurrence in patients undergoing cryoablation (relative risk [RR] = 7.45) or RFA (RR = 18.23) when compared with partial nephrectomy (Kunkle et al, 2008). Treatment failure was also linked to tumor size. However, no significant difference in rates of progression to metastatic disease was observed, regardless of treatment modality (Kunkle et al, 2008). More recently, Ramirez and colleagues (2014) published on 79 patients who underwent RFA of 111 SRMs with a median tumor size of 2.2 cm over a 10-year period and had a median follow-up of 59 months. These patients had an estimated 5-year recurrence-free survival of 93.3%.

Complications

A multi-institutional experience with 148 laparoscopic cryoablation procedures on 144 patients reported a complication rate of 15.5% (Laguna et al, 2009). Significant independent predictors of negative outcomes and complications included tumor size, preexisting cardiac disease, and female gender. A second multi-institutional study investigated complications of both percutaneous and laparoscopic cryoablation and RFA of small renal tumors (Johnson et al, 2004). A total of 139 cryoablations were performed along with 133 RFAs. An overall 11% complication rate was observed, with 1.8% classified as major and 9.2% as minor. Major complications included significant hemorrhage, ileus, ureteropelvic junction obstruction necessitating nephrectomy, urinoma, conversion to open surgery, and death (aspiration pneumonia). In the laparoscopic group (90 patients), a 9% complication rate was reported, with the most common complication being pain or paresthesia at the ablation probe insertion site.

LAPAROENDOSCOPIC SINGLE-SITE SURGERY OF THE KIDNEY

Clinical Experience of Renal Laparoendoscopic Single-Site Surgery

Initially reported for nephrectomy in the urologic literature (Raman et al, 2007), LESS has now been used to perform a wide variety of

Figure 61-41. Laparoendoscopic single-site surgery donor nephrectomy using a purpose-specific device with multichannel instrument access. A 2-mm instrument is also used to aid in retraction, hilar dissection, and extraction.

urologic procedures (Kaouk et al, 2011). Adjunctive 3- to 5-mm subxiphoid ports and 2-mm needlescopic ports have been required in some cases for liver retraction and aiding in laparoscopic suturing. Reported operative times and complication rates have been comparable to those of earlier experiences of traditional laparoscopy (Fig. 61-41), although it should be noted that surgeons attempting LESS renal procedures are often highly experienced in traditional laparoscopy.

The most extensive LESS series are reports of an international multi-institutional effort reporting over 1000 patients, wherein LESS has been used to perform a variety of different urologic surgeries (Kaouk et al, 2011; Autorino et al, 2012). A wide range of procedures have been successfully performed including pyeloplasty, simple nephrectomy, donor nephrectomy, radical nephrectomy, nephroureterectomy, partial nephrectomy, renal cyst decortication, renal cryoablation, simple prostatectomy, radical prostatectomy, radical cystectomy, sacrocolpopexy, adrenalectomy, varicocelectomy, and ureterolithotomy. Most cases highlighted in this extensive experience consist of LESS renal procedures.

The follow-up study focused on the risks of conversion and complications in this urologic LESS experience (Autorino et al, 2012). The authors reported oncologic indications, pelvic surgery, robotic approach, high difficulty score, extended operative time, and intraoperative complications as independent predictors of conversion, in addition to finding that reconstructive procedures, high difficulty score, and extended operative time predicted high-grade complications, which occurred in only 2.4% of the entire cohort, comparable to conventional laparoscopic series.

After gaining substantial experience with LESS techniques, several centers have now reported the use of LESS with more time-sensitive surgeries such as donor nephrectomy and partial nephrectomy. Two randomized studies comparing LESS with conventional laparoscopic donor nephrectomies have shown similar perioperative parameters including operative time, estimated blood loss, rate of transfusion, rate of complications, rate of conversion, and change in eGFR in both studies (Kurien et al, 2011; Richstone et al, 2013). One study demonstrated an increased warm ischemia time with LESS, whereas the other study found no significant difference, and both reports had findings of decreased patient-reported pain

scores in the LESS patient cohort compared with conventional laparoscopy.

The largest series of LESS partial nephrectomies is a multi-institutional consortium of 11 institutions reporting on 190 patients with a mean tumor size of 2.6 cm and median warm ischemia time of 16.5 minutes resulting in a median estimated blood loss of 150 mL (Greco et al, 2013). Of these cases, 36.8% were successfully performed off-clamp. Oncologic outcomes for this patient cohort were published by Springer and colleagues (2014) and demonstrated disease-free survival of 98%, 97%, and 97% at 12, 24, and 36 months and overall survival of 99%, 97%, and 88% at 12, 24, and 36 months, respectively.

Other comparative studies of LESS versus conventional laparoscopic renal surgery have been reported for nephrectomy, yielding similar findings to those of the donor nephrectomy literature wherein LESS is feasible and yields similar perioperative and short-term results to cases in which the conventional laparoscopic approach is used (Raman et al, 2009; Tugcu et al, 2010). Randomized controlled trials comparing LESS with conventional laparoscopy for both nephrectomy and pyeloplasty have shown a significantly earlier return to normal activities, lower visual analog pain scale scores, and lower postoperative use of analgesics (Tugcu et al, 2010; Tugcu et al, 2013).

Robotic Laparoendoscopic Single-Site Surgery

The da Vinci-S Robotic System (Intuitive Surgical) has been used in conjunction with the LESS approach to urologic surgery by a number of groups since the initial report by Kaouk and colleagues (2009b) documenting successful robotic laparoendoscopic single-site surgery (R-LESS) radical prostatectomy, pyeloplasty, and radical nephrectomy. It has been proposed that the benefits of robotic assistance may overcome some of the challenges inherent to LESS, including the limited triangulation needed for precise dissection and tissue manipulation including retraction and reconstruction (Samarasekera and Kaouk, 2013). Extracorporeal “clashing” of robotic arms has been noted since the earliest experience of R-LESS and persists, although it has been lessened with techniques used to “chopstick” or cross the robotic arms and reverse the handedness of the robotic console controls to correct the visual association of the affected instruments within the operative field. R-LESS has been performed using the GelPort/GelPoint laparoscopic access system (Applied Medical, Rancho Santa Margarita, CA) as well as other purpose-built LESS access platforms (Stein et al, 2010; Autorino et al, 2013). Nevertheless, there is a continued need for further advances in the robotic platform designed to facilitate single-site surgery as well as novel, purpose-built robotic instrumentation-friendly access platforms to optimize the ease of use of R-LESS. With widespread availability of operative robotic platforms, R-LESS will potentially be more practical than standard LESS procedures with their inherent technical challenges.

COMPLICATIONS OF LAPAROSCOPIC RENAL SURGERY

Complications are an unavoidable consequence of surgical practice and even the most experienced clinicians will face problems. Organic factors related to the patient, operating room environment, and chaotic forces can lead to an untoward event. Thus, efforts at prevention through knowledge of each given procedure and its potential pitfalls should be maximized. Moreover, patient education about the potential risks of surgery is essential.

Patient selection is important to minimize risk of complications. This needs to be paired with each surgeon’s experience and ability. Several situations require caution when considering a laparoscopic approach. True contraindications include an uncorrected coagulopathy, untreated infection, and hypovolemic shock (Capelouto and Kavoussi, 1993). Previous surgery is not a contraindication to laparoscopic renal surgery. However, prior abdominal surgery may result in intra-abdominal adhesions and increased possibility of bowel injury during insufflation, trocar placement, or

dissection. The initial entry site in these patients should be away from scars and prior surgical fields. If Veress needle access is used for creating the pneumoperitoneum, the desired site of first trocar insertion can be first assessed with placement of a second Veress needle at that site to ensure evacuation of gas suggesting a lack of adhesions or bowel in that area. Also, open trocar placement or a retroperitoneal approach may be necessary to minimize access injuries and avoid adhesions (Hasson, 1971).

Patients with large, dilated loops of bowel from either functional or obstructive ileus should be approached cautiously, because the dilated intestinal segments can limit the working space and may be injured during access, dissection, and trocar site closure (Borten, 1986).

Care is taken to keep anatomic orientation at all times, because confusion in landmarks can lead to catastrophic consequences. Prior surgery or bulky pathology can alter normal anatomic relationships. It is thus necessary to have preoperative imaging studies available in the room. Intraoperative ultrasonography can be a valuable tool to further help identify structures. When visual clues are inadequate to allow safe progress, palpation by hand assistance may provide additional information. Alternatively, open conversion may be indicated.

When complications occur, the consequences can often be minimized through early recognition and appropriate intervention. Laparoscopic renal surgeries share several potential risks with traditional open approaches. However, there are differences in the type and presentation of these complications. It must be kept in mind that all situations are individual, and unique problems may arise and call for innovative actions.

General complications of laparoscopic surgery are covered in Chapter 10; however, specific pitfalls require review. Reported complications of laparoscopic kidney surgery are reviewed in Box 61-1.

BOX 61-1 Reported Complications of Laparoscopic Kidney Surgery
Vascular injury
Adjacent organ injury (liver, spleen, pancreas, bowel, stomach, diaphragm)
Wound infection
Abscess
Seroma
Wound dehiscence
Internal hernia
Incisional hernia
Pulmonary complications (pneumothorax, pulmonary edema, pleural effusion, pneumonia)
Pulmonary embolism
Deep vein thrombosis
Neuromuscular pain
Postoperative bleeding and transfusion
Atrial fibrillation
Myocardial infarction
Adrenal insufficiency
Testicular infarction or ischemia
Epididymitis
Ureteral stricture
Nonelective open conversion
Chylous ascites
Urinoma
Completion nephrectomy (after partial nephrectomy)
Tumor fragmentation
Renal insufficiency (transient or chronic)
Delayed bleeding
Urinary tract infection
Urinary retention

Figure 61-42. Computed tomography (CT) scan taken 9 days after partial nephrectomy when the patient visited the clinic for routine follow-up complaining of distention and worsening abdominal pain for the previous 3 days, low-grade fever, leukopenia, and pain out of proportion at a single trocar site. CT shows dilated loops of large bowel and significant amounts of free air. Exploration revealed a small perforation in the cecum.

The combined incidence of bowel injury in the urologic literature is 0.8%, and injury may occur at any point during the dissection (Schwartz et al, 2010). When reflecting the colon or duodenum, avoid thermal energy adjacent to the bowel. This is the most common cause of unrecognized injury and may not be diagnosed until postoperative day 3 to 5. When recognized intraoperatively, superficial thermal injuries may be oversewn with 3-0 silk suture to imbricate the affected area. Transmural injuries should be debrided and, as with primary sharp injury, may be closed primarily in two layers. The area should be irrigated thoroughly and inspected to rule out a through and through injury. Drain placement is encouraged and oral intake is withheld until bowel function has returned.

One of the most significant complications occurring as a result of laparoscopic surgery is unrecognized bowel injury (Fig. 61-42). Only a small portion of the laparoscopic instrument is in the visual field, so injuries can occur out of the surgeon's view during introduction or retraction of instruments. In the urologic literature, the overall incidence of bowel injury during laparoscopic surgery of the retroperitoneum, both recognized and unrecognized, is 0.65% (Schwartz et al, 2010). Unrecognized injuries result in high-grade complications in 100% of cases in series reporting on laparoscopic bowel injuries. Blunt, sharp, and cautery dissections account for the majority of bowel injuries (60%), whereas access-related injuries are far less common (6%). The presentation of bowel injuries in patients undergoing laparoscopy differs from that described with open surgery. Patients with unrecognized bowel injury after laparoscopy typically have persistent and increased trocar-site pain at the site closest to the bowel injury. The area around this site becomes edematous and doughy in consistency. Signs and symptoms may also include abdominal distention, nausea, diarrhea, anorexia, low-grade fever, persistent bowel sounds, and a low or normal white blood cell count. The patient's condition can rapidly deteriorate to hemodynamic instability and death, if the injury is not recognized and appropriately treated (Bishoff et al, 1999). CT with oral contrast is the initial diagnostic modality of choice (Cadeddu et al, 1997), and

open exploration is usually required to evacuate bowel spillage and perform the necessary repair. In rare cases, when a controlled fistula develops, conservative management with bowel rest and hyperalimentation may be used, but this can take months to resolve.

In reflecting the bowel on the left side, care must be taken to avoid making a hole in the mesentery. Any mesenteric defects should be closed because postoperative bowel herniation is possible (Regan et al, 2003). During closure of the mesentery, care also should be taken to avoid compromising the vascular supply to the colon. Retractors not in the operative field may also injure the bowel, and one should check for inadvertent injury at the conclusion of the procedure.

Vascular injuries are the most common complication of urologic laparoscopy (Permpongkosol et al, 2007). Life-threatening vascular injuries can occur during laparoscopic renal surgery and usually occur during dissection of the renal hilum. Injury to arteries, veins, branches, and accessory vessels can result in bleeding that may require conversion to open surgery. The renal vein can have multiple branches that can easily be torn. Care should be taken in ensuring ligation and transection without tension. Venous bleeding can be brisk and quickly lead to hemodynamic instability. Often, applying direct pressure with gauze for several minutes will be sufficient to control venous bleeding. Resist the temptation to continually explore the area of venous bleeding, if all is quiescent once the gauze has been removed. On the right side, the vena cava can be injured. Avulsion of the gonadal or adrenal vein can cause significant bleeding. If a hole is visible, placement of a clip or suture may be attempted once a grasper has controlled the situation. Blind clip placement or suturing can lead to a worsening of the situation and additional complications. Again, direct pressure with gauze over several minutes may abate bleeding. Dissection may continue with the gauze in place.

Arterial injuries can occur when structures are not fully identified before transection. Also, past pointing of scissors can cut an underlying vessel. If the opening is identified, suture placement or clips may be used for control. A hand may be placed in a lower abdominal midline incision to hold pressure if bleeding is brisk. In this manner, laparoscopic suturing or open conversion can proceed in a controlled manner.

Cases of inadvertent stapling of important anatomic structures have been reported. The vena cava and aorta have been mistaken for the renal vessels (McAllister et al, 2004). Several instances of transection of the small mesenteric artery (SMA) or contralateral renal vessels have also occurred. This can occur readily with the novice who is unfamiliar with the retroperitoneal approach. Unfortunately, many of these are not recognized intraoperatively and the risk of mortality is high. The best way to avoid this complication is through continuous anatomic orientation and vigilant self-questioning.

Equipment failure can result in bleeding. A multi-institutional review of endovascular stapler complications showed a malfunction rate of 1.8% (10 of 565), with 8 cases involving the renal vein and 2 cases the renal artery (Chan et al, 2000). Blood loss resulting from the malfunction was 200 to 1200 mL. Conversion to open surgery for hemostasis was required in 20% of the malfunction cases. Stapler failure was caused directly by the instrument in 3 cases and had preventable causes in 7 cases. Preventable causes included stapling over clips or incomplete transection resulting from incorrect placement. The abdominal cavity should be inspected for bleeding at the conclusion of surgery, and decreasing intraperitoneal insufflation pressures may assist in unmasking occult venous bleeding. Common areas of postoperative intra-abdominal bleeding include the bed of the dissection, adrenal gland, mesentery, gonadal vessels, and ureteral stump.

Postoperative hemorrhage can occur after partial nephrectomy. Hypotension with associated tachycardia and a drop in hematocrit may imply postoperative bleeding. After partial nephrectomy, an arteriovenous malformation or pseudoaneurysm may form (Benway et al, 2009b; Shapiro et al, 2009; Hyams et al, 2011; Montag et al, 2011). These patients have persistent gross hematuria, hypotension, and tachycardia. If there is uncertainty

regarding the source of hemorrhage, CT scanning may be appropriate in identifying the site of bleeding. However, in the majority of patients, especially in a delayed hemorrhage setting with gross hematuria, immediate renal angiography with embolization of the bleeding site is indicated (Montag et al, 2011).

Persistent urine leakage may occur after a partial nephrectomy or cyst ablation. Unless there is distal obstruction to the site of leakage, most will resolve with conservative therapy after several weeks (Meeks et al, 2008). After approximately 1 week, a controlled fistula develops, and the drain can be taken off continuous suction and checked intermittently to be sure fluid is not accumulating. If conservative management fails, as in cases of distal obstruction, additional intervention may be required, such as percutaneous drainage of a perinephric urinoma or a combination of ureteral stenting and bladder decompression.

Upper pole renal dissection can result in diaphragmatic injury. This is usually immediately recognized because peak airway pressures suddenly increase, and ventilation of the patient becomes difficult. The diaphragm can be seen billowing via laparoscopic inspection. Immediate treatment is needed to prevent development of a tension pneumothorax. The diaphragm can be sutured directly while a central line catheter is placed into the ipsilateral anterior second intercostal space and placed to a water seal. At the conclusion of the procedure, the patient is ventilated, a chest radiograph is obtained, and, if the pneumothorax is resolved, the catheter is removed. When significant pneumothorax persists, a chest tube can be inserted (Del Pizzo et al, 2003; Aron et al, 2007).

On the left side, splenic and pancreatic injuries may occur. Bleeding from the spleen is usually controlled with topical hemostatic agents and argon beam coagulation (Canby-Hagino et al, 2000; McGinnis et al, 2000). Injuries to the pancreas may be insidious, and inspection is needed at the conclusion of surgery. Superficial pancreatic injuries can be managed conservatively with drain placement. Deeper injuries may require formal repair or isolation of the segment with a GIA stapler (Varkarakis et al, 2004b). Right-sided dissections may cause injury to the liver or gallbladder. Liver injuries are managed with topical hemostatic therapy and argon beam coagulation. Gallbladder injuries are best managed by concurrent cholecystectomy.

Patients undergoing laparoscopic renal surgery are at risk of intravascular volume overload if fluid replacement is not modified relative to open surgery. The laparoscopic approach is associated with far less insensible fluid loss compared with open procedures, and there is also a vascular-mediated oliguria. Accordingly, urine output should not be a barometer of fluid resuscitation status as it is with open surgical procedures. Typically, IV fluids should be minimized with the exception of laparoscopic donor nephrectomy. Aggressive replacement can result in volume overload in patients with diminished cardiac reserve and can result in postoperative congestive heart failure. Poor urine output or hemodynamic instability in the postoperative period should initiate an evaluation to rule out bleeding; if the workup is negative, diuresis can be induced if clinically indicated.

Several authors have reported cases of chronic pain syndrome or nerve injury after LRN. Patients may experience a burning discomfort in the ipsilateral flank; paresthesias around port sites or over the thigh and upper extremity can occur (Wolf et al, 2000; Oefelein and Bayazit, 2003). In a series of 381 laparoscopic donor nephrectomies, ipsilateral orchialgia was reported in 10% of patients (Kim et al, 2003). Onset of pain occurred at a mean of 5 days after surgery (range 6 to 52 months), and at 6 months 50% had complete spontaneous resolution. Thigh paresthesias may be avoided by preserving the psoas fascia during posterior renal dissection. Additional reported complications include incisional hernia after intact specimen removal, port-site hernia, prolonged ileus, pulmonary embolus, and pneumonia.

In a multi-institutional review of 185 patients, Gill and coworkers (1995) reported an overall complication rate of 12% for benign disease, with 5% of patients requiring conversion to open surgery. In this series the incidence of complications decreased markedly with increasing experience. In fact, 70% of

the complications occurred during the first 20 cases at each institution. A learning curve of approximately 20 laparoscopic nephrectomy cases is also supported by other reports (Keeley and Tolley, 1998; Rassweiler et al, 1998b; Fahlenkamp et al, 1999). In a series of laparoscopic partial nephrectomies reported in 2010, the complication rate continued to decrease even after 750 cases (Gill et al, 2010). This implies a longer learning curve for more complex procedures.

In a series of 482 laparoscopic nephrectomies (444 procedures for benign disease) performed by 20 surgeons at 14 different European medical centers, a 6% overall complication rate was reported, with 10% of the cases converted to open surgery (Rassweiler et al, 1998b). The majority of patients converted to open surgery had infectious causes of renal abnormality as the leading indication for kidney removal. Bleeding was the most common cause of open conversion in these cases, followed by the surgeon's inability to visualize the renal hilum for safe, complete dissection.

In series comparing open, hand-assisted, and laparoscopic nephrectomy for malignancy, the complication rates were 10%, 17%, and 12% respectively ($P = .133$) (Chan et al, 2001; Shuford et al, 2004).

Two comparative studies examining complication rates in the elderly population—older than 75 and older than 80 years—found no difference in surgical or long-term morbidity when compared with younger patient populations (Varkarakis et al, 2004a; Thomas et al, 2009). In patients at high risk for perioperative complications, as determined by an American Society of Anesthesiologists score greater than or equal to 3, there were no significant differences in complication rates among hand-assisted, laparoscopic, and open radical nephrectomy (Baldwin et al, 2003).

PENETRANCE OF MINIMALLY INVASIVE RENAL SURGERY AMONG UROLOGISTS

Studies have demonstrated the serious underutilization of laparoscopic and nephron-sparing techniques (Permpongkosol et al, 2006b; Miller et al, 2008; Liu et al, 2014). After variables such as demographics, tumor size, and comorbidities were controlled for, surgeon-attributable factors were consistently the most significant predictor of the type of surgery performed. However, there has been a noticeable trend toward increased implementation of partial nephrectomy, both open and laparoscopic, and a trend toward laparoscopic and robotic-assisted laparoscopic renal surgery over time (Poon et al, 2013). Laparoscopic procedures such as cholecystectomy and appendectomy are quite commonplace and were rapidly adopted by general surgeons. Historically, urologists have been receptive to new technology, a fact clearly demonstrated by the rapid increase in the number of robotic prostatectomies performed in the United States. However, the relatively slower pace of widespread adoption of laparoscopic renal surgery, despite its longevity and proven benefits, would suggest additional barriers to the diffusion of its implementation. A complex array of reasons may account for this observation, including the differential incidence of kidney and prostate cancer, marketing of robotics, referral patterns, and consumer demand (Richstone and Kavoussi, 2008). The incorporation of robotic assistance in laparoscopic renal surgery may facilitate broader implementation of minimally invasive renal surgery (Patel et al, 2013).

SUMMARY

Laparoscopy is the preferred treatment modality for many types of renal pathology. Patients have undoubtedly gained from the benefits laparoscopy offers in terms of perioperative morbidity without sacrificing therapeutic outcomes. As surgical tools continue to evolve, even more minimally invasive options may become more pervasive and potentially offer additional perioperative benefit to patients.

KEY POINTS

- Laparoscopy can be used to treat most renal pathology with efficacy equal to that of open surgery while resulting in less pain, shorter convalescence, and improved cosmesis.
- Basic principles of oncologic surgery must be maintained when using a laparoscopic approach to treat renal tumors.
- Unrecognized bowel injuries are associated with high-grade complications including high mortality. It must be recognized that the presentation of unrecognized bowel injuries in patients undergoing laparoscopy may differ from that described with open surgery. Presentation is typically characterized by normal to low white blood count, focal abdominal pain (often worst at the trocar site nearest the injury), mild ileus, and lack of fever.

New Ablation Modalities

Conclusions

The incidence of localized renal cell carcinoma (RCC) is rising as a result of the increasing use of cross-sectional imaging.

According to the Surveillance, Epidemiology, and End Results Program (SEER), in North America the age-adjusted incidence rate of kidney cancer was estimated at 15.6 per 100,000 person-years in 2012, representing a greater than twofold increase since 1975 (National Cancer Institute, 2012). Along with the increasing incidence in the diagnosis of renal masses, there has been a parallel down-staging of newly detected renal masses, such that more than 70% are small and organ confined (clinical stage T1) (Volpe et al, 2004; Chen and Uzzo, 2011). The overall result is a paradigm shift in the management of RCC over the last decade, with an increasing focus on minimally invasive treatment and nephron-sparing surgery. Accordingly, in addition to cancer-specific survival (CSS), emphasis is now placed on preservation of renal function and avoidance of treatment-related morbidity in the management of early-stage RCC. Therefore the 2009 American Urologic Association (AUA) guidelines for the management of clinical stage 1 renal masses recommends nephron-sparing surgery as standard of care, with consideration of ablative therapies as valid alternatives for older patients or those with substantial comorbidities (Novick et al, 2009).

Partial nephrectomy is the gold standard for the treatment of small renal tumors because it provides comparable oncologic outcomes (>95% CSS) compared with radical nephrectomy and is associated with improved preservation of renal function, superior cardiac outcomes, and improved overall survival (Thompson et al, 2008; Huang et al, 2009; Zini et al, 2009). Moreover, nephron-sparing surgery avoids overtreatment of indolent or benign tumors, a particularly germane concern given that nearly 20% of small renal masses are pathologically benign, 55% to 60% are malignant but display indolent behavior, and only 20% to 25% have highly aggressive histologic features (Frank et al, 2003; Russo, 2008; Thompson et al, 2009). Irrespective of an open or laparoscopic surgical approach, nephron-sparing surgery is underused in the United States owing to the comparative risks and attendant technical demands associated with the procedure (Abouassaly et al, 2009). Recent SEER data found that partial nephrectomy use is increasing, yet 72% of patients with localized renal tumors still undergo radical nephrectomy (Smaldone et al, 2012). Thus, to increase the number of patients offered nephron-sparing surgery and broaden the minimally invasive treatment options available to patients with small renal tumors, energy-based, in-situ tumor ablation technologies were introduced in the 1990s.

Focal ablative therapies offer several advantages compared with extirpative surgery. First, these modalities are less technically demanding than open, laparoscopic, or robotic partial nephrectomy, because renorrhaphy and hilar dissection are not obligatory.

Consequently, renal tumor ablation is associated with shorter convalescence and fewer complications than extirpative surgery (Desai et al, 2005). Equally important, several studies clearly demonstrated minimal impact on postablation renal function, with comparable or better postoperative renal function found when compared to that with partial nephrectomy (Shingleton and Sewell, 2003; Lucas et al, 2008; Raman et al, 2008b). Finally, all of the ablation modalities offer treatment versatility because they can be deployed in open, laparoscopic, or percutaneous procedures. Given these advantages, well-recognized indications for ablative treatment include patients with small renal tumors who are either poor surgical candidates or at risk for renal insufficiency, including patients with solitary kidneys, bilateral renal tumors, hereditary syndromes such as von Hippel-Landau disease, and renal insufficiency. However, because of the excellent results with ablation in these selected patients, there is now growing experience with the treatment of the sporadic small renal tumors in healthy patients (Stern et al, 2009). Together with improved treatment guidance systems, more robust operator experience, and improved patient selection, renal ablative technologies are now a viable treatment alternative for small renal tumors.

CRYOABLATION

Background and Mode of Action

Cryoablation (CA), or cryotherapy, refers to the practice of using extreme cold temperatures to treat a wide variety of pathologic conditions. The use of cold therapy in medicine can be traced back to the early Egyptians, who used cold to treat inflammatory conditions as early as 2500 BC. However, CA was not used with a goal of tissue destruction until the mid-1800s, when an English physician, Dr. James Arnott, described using a combination of ice and salt to obtain temperatures (-18°C to -24°C) sufficient to treat breast, cervical, and skin cancers (Arnott, 1850). Over the course of the ensuing decades, multiple investigators described the use of cooled gases for treatment of various skin conditions, beginning with liquified air (-190°C), followed by solidified carbon dioxide (-78.5°C), liquid oxygen (-182.9°C), and then eventually liquid nitrogen (-196°C) (Freiman and Bouganin, 2005). In 1963, Cooper and Lee developed the first modern cryoprobe using pressurized liquid nitrogen passed through a three-channel probe (one inflow and two outflow) to achieve controlled temperatures of -196°C (Cooper, 1963). This revolutionary probe opened the possibility of treating less accessible areas rather than relegating cryotherapy solely to superficial areas such as the skin.

Although Cooper's design allowed for intra-abdominal treatment of large volumes, its use was limited by an inability to control

or monitor the extent of the cryolesion. Without the availability of intraoperative imaging to visualize the expanding frozen tissue or “ice ball” physicians routinely relied on physical examination to monitor treatment, such as digital rectal examination during prostate cryotherapy, which often led to irreparable collateral damage (Weber and Lee, 2005). In the mid-1980s, Onik and colleagues (1984, 1985) discovered that the cryogenic ice-tissue interface was highly echogenic on ultrasonography when used in the liver, allowing for the fusion of CA with real-time image guidance and opening the door for controlled treatment of intra-abdominal malignancies. Further animal studies confirmed a close correlation between the sonographically visible ice ball and the zone of cell death, providing a reliable and reproducible method of targeting and destroying tumors without attendant collateral damage (Steed et al, 1997; Campbell et al, 1998; Weber et al, 1998).

Although the fusion of the nitrogen-based cryoprobe and ultrasound guidance improved the treatment of intra-abdominal tumors, the next significant breakthrough came with the development of argon gas–based probes, which relied on the Joule-Thomson principle (low temperatures are achieved by the rapid expansion of high-pressure, inert gas) to generate temperatures of -185.7°C within the treatment tissues. In addition to providing a reliable target temperature, argon-based systems are more efficient than nitrogen-based probes, with target temperatures reached faster and with a steeper internal thermal gradient (Rewcastle et al, 1999). The majority of commercially available CA units now employ argon gas–based systems (CryoHit, Galil Medical, Plymouth Meeting, PA; CryoCare, CryoCare CS, Endocare, Irvine, CA; SeedNet, Oncura, Philadelphia, PA).

Tissue destruction during CA occurs during both the freezing and thawing processes. Rapid freezing in the area closest to the cryoprobe forms ice crystals within the intracellular space that cause direct cellular injury through mechanical trauma to plasma membranes and organelles, leading to subsequent cell death mediated by ischemia and apoptosis (Mazur, 1977; Ishiguro and Rubinsky, 1994; Hoffmann and Bischof, 2002; Baust and Gage, 2005). As the freezing process expands further from the cryoprobe, the cooling process is slower, which encourages extracellular ice crystals to form and leads to a depletion of extracellular water and an osmotic gradient that causes further intracellular damage through dehydration and membrane rupture. During the thawing phase, extracellular osmolarity decreases as ice crystals melt, allowing an influx of water back into cells, which causes cellular edema and further disruption of cell membranes (Erinjeri and Clark, 2010). In addition to direct cellular damage, injury to blood vessel endothelium during the freezing process results in platelet activation, vascular thrombosis, and tissue ischemia (Weber et al, 1997; Kahlenberg et al, 1998; Rupp et al, 2002). The summative pathologic consequence of treatment is coagulative necrosis, cellular apoptosis, and eventual fibrosis and scar formation.

Treatment Temperature

Tissue destruction during CA requires a certain threshold temperature, which is unique to the cell type and cellular environment of the target tissue. Whereas normal renal parenchyma is typically destroyed at -19.4°C , small animal models of CA indicate that temperatures as low as -50°C may be necessary to guarantee complete cellular death of cancerous tissue because of its more fibrous nature (Chosy et al, 1998; Gage and Baust, 1998; Larson et al, 2000). Therefore the preferred target tissue temperature during CA is at or below -40°C . Importantly, the temperature of the progressing ice ball is not uniform, with temperatures increasing the further the distance from the cryoprobe. Campbell and colleagues (1998) measured intrarenal temperatures during CA and referenced these to the leading edge of the ice-tissue interface. At the edge of the ice ball, the temperature was measured at 0°C , correlating with the onset of the freezing process. Temperatures of -20°C were reached 2.0 mm within the ice-tissue interface, while temperatures consistently below -20°C were not reached until 3.1 mm inside. Based on these findings, most authors advocate

creating an ice ball treatment zone that is at least 5 to 10 mm beyond the edge of the target lesion. Alternatively, small temperature probes may be positioned around the tumor periphery to ensure that adequate treatment temperatures (-40°C) are achieved (Rukstalis et al, 2001). Depending on the size of the lesion and the type and size of probe used, reaching the appropriate target temperature within the entire mass may require the use of multiple cryoprobes (Breen et al, 2013). Additionally, freezing is subject to the “heat sink” phenomenon, in which large blood vessels adjacent to the tumor may dissipate ice formation and require more extreme temperatures or longer periods of cooling (see section on radiofrequency ablation and heat sink in next section for further details).

Freeze-Thaw Cycles

In-vivo animal studies initially demonstrated adequate cell kill in normal tissue employing a single freeze-thaw cycle (Weber et al, 1997). However, further studies on implanted tumor cells in mice, then in dogs, found that multiple freeze-thaw cycles promoted a larger and more adequate area of liquefactive necrosis, improving subsequent cure rates (Neel et al, 1971; Woolley et al, 2002). Therefore, when treating renal malignancies, the current recommendation is to perform a double freeze-thaw cycle to ensure complete cellular death. The thawing process is also instrumental in cellular death and may be performed in a passive or active manner. Passive thawing, which relies on the ice ball melting without any intervention after the cessation of argon gas through the cryoprobe, is more time-consuming than active thawing, where helium gas (rather than argon) is forced through the cryoprobe creating a warming effect secondary to the Joule-Thomson principle. Although clearly more efficient, there are conflicting data on whether an active thaw is as effective as a passive thaw (Woolley et al, 2002; Klossner et al, 2007). In addition to decreasing operating room time, an active thaw during at least the second thaw cycle may allow the surgeon to more rapidly address post-treatment bleeding (White and Kaouk, 2012).

Duration of Treatment

The duration of treatment to produce complete cellular death in humans is unknown. Auge and colleagues (2006) performed a prospective study in nine female farm pigs with CA performed for 5, 10, or 15 minutes. Although all lesions demonstrated complete cellular necrosis 5 mm from the probe, only animals treated for 10 or 15 minutes had necrosis extending 10 mm or more beyond the probes. Furthermore, animals treated for only 5 minutes had excessive bleeding, whereas those treated for 15 minutes had an increased risk for tumor fracture and subsequent hemorrhage. Based on these findings, most contemporary series use a freeze cycle of 8 to 10 minutes (Breen et al, 2013; Kim et al, 2013).

KEY POINTS: CRYOABLATION

- CA employs argon gas–based systems to achieve treatment temperatures of less than -40°C through the Joule-Thomson principle.
- CA of renal tumors should be performed under real-time imaging, with the treatment area approximately 5 to 10 mm beyond the margin of the tumor.
- A double freeze-thaw cycle, each 8 to 10 minutes in duration, is currently the standard of care during renal tumor CA.

RADIOFREQUENCY ABLATION

Background and Mode of Action

Radiofrequency ablation (RFA) refers to the use of radiofrequency energy to heat tissue to the point of cellular death. RFA uses monopolar alternating electric current that is delivered directly into the

target tissue at a frequency of 450 to 1200 kHz, leading to vibration of ions within tissue and resulting in molecular friction and heat production. Increasing temperature within the target tissue leads to cellular protein denaturation and cell membrane disintegration (Hsu et al, 2000; Tracy et al, 2010). Importantly, heat is not directly supplied by the probe itself, but rather by the agitation of ions within the tissue (Cosman et al, 1984). Although not as old as cryotherapy, study of the effect of radiofrequency energy dates back over 100 years to 1891 when d'Arsonval described the ability of radiofrequency waves to heat living tissue. Without a clear understanding of the technology and an inability to effectively control the energy, the use of radiofrequency energy in surgery did not become more mainstream until 1928, when Cushing and Bovie developed the electrocautery knife. Using radiofrequency energy they described an ability to cauterize or cut tissue, ushering in the development of the modern-day electrocautery probe, which desiccates tissue at the point of contact when alternating current passes through the patient and then dissipates to a remotely placed grounding pad on the patient's lower extremities. These principles led to further development of RFA and opened the door for use in a broader number of surgical procedures (Organ, 1976).

In 1990 two individual groups of researchers simultaneously reported the development of probes that could be used for percutaneous ablation (McGahan et al, 1990; Rossi et al, 1990). These probes consisted of a layer of insulation down to an exposed metal tip, which allowed for percutaneous passage of the needle to deeper target tissues. Using these needles, the amount of tissue destruction could be controlled along the central axis of the lesion by adjusting the length of the exposed, uninsulated portion of the needle. Although effective in ablating along the long axis of the lesion, these initial probes were limited in their ability to create circumferential tissue damage, preventing their use in lesions greater than 1.5 cm. Further refinements using these initial designs led to the development of modern RFA generators and probes, which are capable of treating larger and more complex lesions.

Variations in Radiofrequency Ablation Equipment

RFA can be performed with either a temperature-based or impedance-based monitoring system. Temperature-based systems work by measuring tissue temperatures at the tip of the electrode and are based on achieving a specific temperature for a given period. These systems accurately measure the temperature of the tissue at the electrode tip; however, they do not measure the temperature of the surrounding parenchyma. Alternatively, impedance-based systems measure the tissue impedance (resistance to alternating current) at the electrode tip and are based on achieving a predetermined impedance level that indicates complete tissue ablation. Although these systems are able to measure actual tissue desiccation at the electrode tip, they have been associated with incomplete ablation in animal models (Gettman, 2002a). **There are no explicit clinical data that support the superiority of impedance or temperature-based systems.**

The original ablation probes, which were designed as single electrode monopolar probes controlled by varying the exposed uninsulated tip, were capable of treating tumors no greater than 2 cm (McGahan et al, 1993). Therefore the treatment of larger tumors or the acquisition of an adequate tumor margin often required additional probes or re-treatment of overlapping regions. Multiple systems have been developed in an attempt to achieve a larger overall treatment volume. LeVeen (1997) introduced an insulated monopolar probe (Boston Scientific, Natick, MA) with 12 deployable tines that function as radiofrequency antennas for the wider dispersion of current. These tines are deployed in an umbrella shape to create a spherical lesion. When high impedance is encountered at one prong, current is redirected to areas of lower impedance. The Christmas tree-shaped RITA device (AngioDynamics, Queensbury, NY) uses thermistors embedded in five of the nine electrical tines to modulate energy based on the temperature of each electrode as well as the average temperature of the electrodes in aggregate. Finally, the Valleylab system (Mansfield, MA) uses an

impedance-based system composed of a single 17-gauge ("cool tip") electrode that is cooled internally with chilled saline to prevent charring of tissue adjacent to the probe. A direct comparison of these systems in the porcine liver demonstrated larger zones of ablation with the "cool tip" systems, more spherical ablation volumes with the 12-tine electrodes, and better reproducibility with the 9-tine electrodes (Pereira et al, 2004). Clinical validation studies have suggested more complete necrosis and superior treatment outcomes with multitine electrodes (Rossi et al, 1998; Curley et al, 2000; Rehman et al, 2004).

Another major classification in RFA technology is the differentiation between "dry" and "wet" RFA. As tissue desiccation increases in the target lesion, the charring effect (carbonization) on tissue leads to increased impedance and resistance to the alternating current of the electrode, limiting the size of the ablation zone with a single electrode to less than 4 cm. "Wet" RFA probes deliver a constant saline infusion into the tissue and in proximity to the probe to lower the temperature at the probe tip, thus mitigating the charring effect and corresponding premature rise in impedance, allowing for larger zones of ablation (Goldberg et al, 1996; Lorentzen et al, 1997; Collyer et al, 2001; Pereira et al, 2004). Additionally, interstitial hypertonic saline infusion forms a virtual "liquid electrode" beyond the metal electrode so that the total electrode surface area is augmented (Ni et al, 1999). **Although lesions tend to be larger using "wet" RFA, there is less control of the exact size of ablation, which may lead to overtreatment of the target zone and disruption of adjacent normal parenchyma (Frich and colleagues, 2005).**

Radiofrequency energy also can be delivered through either bipolar or monopolar electrodes. Compared to traditional monopolar radiofrequency devices, which work based on electrical transmission through the exposed probe tip with dissipation to a grounding pad on the skin of the patient, bipolar radiofrequency devices generate current between two separate electrodes (one active and one negative), within the target tissue. The purported advantage of bipolar energy is that significantly higher temperatures are induced compared with those of monopolar devices (Nakada et al, 2003). In addition, heat is generated not only at the active probe but also adjacent to the ground needle and between the two electrodes (McGahan et al, 1996), resulting in a focus of coagulation necrosis that is larger than with a conventional monopolar electrode. The use of two separate electrodes, however, produces an elliptical area of coagulation necrosis rather than spherical; because most renal tumors are spherical, this technology has not been widely adapted for RFA of renal masses.

Treatment Temperature

The ability of RFA to ablate the target tissue relies on power delivered to the probe, the maximum temperature obtained, and the duration of the ablation (McGahan and Dodd, 2001). As stated, alternating radiofrequency current creates cellular agitation and, as a result of electrical impedance of the tissue, local heating. Provided that electrical impedance remains low, an expanding sphere of tissue damage emanates outward from the treatment probe. If current is administered too rapidly or the amount of radiofrequency energy applied is too high, charring occurs, which reduces the water content of the tissue. Charring and dehydration then may lead to increased electrical impedance, blocking energy transfer and halting the heating process (Djavan et al, 2000; Finelli et al, 2003). To prevent this phenomenon, which may lead to incomplete or nonuniform ablation, target temperatures during RFA are generally kept at or below 105°C. It is also important to reach a minimum target temperature at which cellular death occurs. In in-vitro studies using human prostate tissue, Bhowmick and associates (2004a, 2004b) achieved irreversible cell injury when benign and malignant cell lines were heated to 45°C for 60 minutes, 55°C for 5 minutes, and 70°C for 1 minute. Similarly, Walsh and colleagues (2007) found that even short exposures at temperatures higher than 70°C are lethal to human RCC in vitro. **To maximize cellular death without carbonization, most modern**

temperature-based generators are programmed to reach a target temperature of 105°C, and ablation should not be considered successful unless a minimum of 70°C is reached during the treatment cycle. Impedance-based systems are typically started at 40 to 80 W and increased at 10 W/min to a maximum of 130 to 200 W until an impedance of 200 to 500 ohms is reached.

The ability of the radiofrequency (or CA) to reach its target temperature within the tissue depends not only on the probe itself and the energy delivered but also on the surrounding treatment environment (Goldberg et al, 2000). In particular, when the target zone is highly vascularized or is adjacent to large vessels, thermal energy is preferentially dispersed to the comparatively cooler blood within these vessels. This heat sink effect may therefore spare tumor cells in close proximity to large blood vessels and lead to treatment failures. Temporary renal ischemia during RFA experimentally increases the size of the initial treatment lesion and shortens the time to reach target temperature (Corwin et al, 2001). However, hilar occlusion is not currently recommended because of the risk for arterial thrombosis and ischemia-reperfusion injury to normal parenchyma. To prevent complications of vascular clamping, some authors advocate selective arterial embolization when performing RFA. Hall and colleagues (2000) reported an innovative combination of embolization with polyvinyl alcohol and percutaneous RFA in a 67-year-old patient with a 2.5-cm × 3.0-cm tumor in a solitary kidney. A computed tomography (CT) scan performed at 8 weeks after ablation showed a complete lack of contrast enhancement in the treated area. At 3 months after ablation, a biopsy revealed fibrous tissue and necrotic cellular debris with no evidence of malignancy. The authors have successfully employed this same technique in a few central or large (>4 cm) tumors to reduce the circulatory heat sink.

Although most studies show cellular death with a single RFA treatment, studies in animals using CA have demonstrated improved cell death with multiple cycles. Therefore, when employing a temperature-based system, we typically recommend using two separate RFA cycles separated by a minimum 30-second cool-down period (Park et al, 2006a).

Intraoperative Monitoring

Although it is possible to visualize placement of the RFA probe using ultrasonography, magnetic resonance imaging (MRI), or CT guidance, there is currently no reliable manner to evaluate the zone of treatment radiographically (Rendon et al, 2001; Renshaw, 2004). In contrast to CA, where the expanding ice ball indicates the zone of treatment, the RFA treatment zone is determined solely by the probe choice, accurate placement, and measurement of electrical impedance or temperature (embedded thermistors) measured by the generator itself. An alternative method, which also may be used with CA, is to place nonconducting temperature probes around the periphery of the tumor or at the deep margin to measure real-time treatment temperatures independent of the RFA device. Using this method, Carey and Leveillee (2007) demonstrated 100% clinical success in treating tumors up to 5 cm in diameter. Experimental imaging modalities, including real-time contrast-enhanced ultrasonography (Johnson et al, 2005; Chen et al, 2013) and magnetic resonance elastography (Li and colleagues, 2013) have shown some promise experimentally, but have not been properly evaluated in the clinical setting. The successful ablation of a renal lesion with RFA therefore is highly dependent (likely more so than with CA) on exact probe placement, and outcome is typically determined only by feedback from the generator, thermal probes, the presence of gas bubbles within the tumor, and the absence of contrast enhancement during percutaneous CT-guided RFA.

SURGICAL TECHNIQUE

Transperitoneal and Retroperitoneal Laparoscopic Renal Cryoablation and Radiofrequency Ablation

See Chapter 61 for these modalities.

KEY POINTS: RADIOFREQUENCY ABLATION

- Transfer of radiofrequency energy generates ionic friction and agitation within tissue that results in heating. When temperatures exceed 60°C, irreversible coagulative necrosis and tissue desiccation occurs.
- Treatment may be either thermal based or impedance based.
- Real-time monitoring of ablation depends on measurement of electrical impedance and temperature rather than visual or radiographic cues.

Percutaneous Renal Cryoablation and Radiofrequency Ablation

Depending on treating physician preference, percutaneous tumor ablation is performed under either conscious sedation with local anesthesia or general endotracheal anesthesia. Regardless, the procedure is generally performed on an outpatient basis or 23-hour observation. General endotracheal anesthesia enables control of respiration during probe placement and tumor biopsy that may translate into more accurate targeting and improved overall outcomes (Gupta et al, 2009). Conversely, conscious sedation minimizes the morbidity and time of the procedure. After administration of intravenous prophylactic antibiotics, the patient is positioned in either a prone or modified flank position on the CT gantry, with the choice of position largely dictated by the tumor location. CT guidance is by far the preferred and most common targeting technique, although ultrasound and magnetic resonance guidance also have been reported (Shingleton and Sewell 2001; Davis et al, 2012).

A noncontrast CT image is obtained first to confirm tumor size and position in the prone or lateral position, and a contrast-enhanced CT image is then often obtained to better delineate the tumor. A radiographic grid placed on the patient's skin can help localize placement of the needle. A 20-gauge "finder needle" or access sheath may be inserted under CT guidance near the expected location of the tumor, with position confirmed through repeated imaging. Using this finder needle as a guide, the ablation probe(s) is then positioned to treat the tumor. The number of probes and the duration of treatment are determined based on lesion size in accordance with the manufacturer's recommendations. Serial imaging is used to confirm the placement of all treatment probes/tines. If a tumor biopsy has not been performed, an 18-gauge core biopsy needle is inserted percutaneously and positioning is again confirmed with repeat imaging. Biopsy specimens are obtained and sent for permanent section before the initiation of therapy. Importantly, the treatment probes should be placed into the tumor before the biopsy because perinephric hematoma formation may obscure visualization of the tumor. Probe and biopsy needle positioning and adjustments are all performed with breath holding to standardize the position of the mobile kidney with each sequential pass of the needle.

Monitoring of treatment efficacy during CA employs imaging of the ablation zone. Although each cryoprobe tip reaches temperatures of -140°C to -190°C, there is a steep temperature gradient that falls to 0°C at the edge of the ice ball. Temperatures of less than -20°C are achieved at a distance of 3.1 mm inside the edge of the ice ball (Campbell et al, 1998). Because tumor cell death is reliably achieved at target temperatures of -40°C (Campbell et al, 1998), the ice ball should propagate 5 to 10 mm beyond the tumor margin to ensure complete treatment. The ice ball appears as a distinct hypodense zone on CT imaging (Fig. 62-1). As previously mentioned in the section on mechanism of action, two freeze-thaw cycles are performed to obtain more complete tissue necrosis (Woolley et al, 2002). Unlike RFA, with which lesions are typically treated for a predetermined period, there is no standard duration for a freeze cycle as long as the intended ablation zone size is attained. Ten minutes is commonly used during the initial cycle, and the second cycle is generally shorter (6 to 8 minutes) based on

Figure 62-1. Percutaneous cryoablation. A, Preoperative imaging demonstrates a 2.6-cm exophytic renal cell carcinoma on the posterior aspect of the right kidney. B, Intraoperative image during percutaneous ablations shows low attenuation area corresponding to the ice ball. animal evidence demonstrating inadequate necrosis at 5 minutes and increased tissue fracture at 15 minutes. Thus 10-minute freeze cycles represent an optimal compromise with adequate tumor necrosis and fewer complications (Auge et al, 2006). Each freeze cycle is followed by either an active (helium-based) or passive thaw. Although there is conflicting evidence regarding an active versus passive thaw, some authors suggest an active thaw during at least the second thaw cycle to decrease operative time and allow the surgeon to more rapidly address post-treatment bleeding (White and Kaouk, 2012). After the second cycle thaw, the probe is gently twisted, and, if there is no resistance, it is removed atraumatically. A contrast-enhanced CT is repeated after treatment to assess completeness of ablation and rule out complications.

Monitoring of treatment efficacy during RFA employs measurement of tissue temperature or impedance, using either single multi-

tined probes (with incorporated thermistors) or multiple single-shaft probes that measure tissue impedance as the end point. At our institutions, a 14-gauge Starburst XL (AngioDynamics, Queensbury, NY) RFA probe is deployed and its position is adjusted to ensure complete lesion coverage plus a peritumoral margin of at least 5 mm (Fig. 62-2). This is done using serial limited CT scans through the kidney employing 3-mm cuts. When necessary, after probe positioning, an 18-gauge CT-guided core biopsy is obtained as previously described. Ablation cycles of 5, 7, and 8 minutes at a target temperature of 105°C are then delivered for tine deployments of less than 2 cm, 2 to 3 cm, and 3 to 4 cm, respectively. After a 30-second cool-down, a second cycle of similar duration is performed. During the initial and secondary cool-down cycles, the passive tissue temperature in each quadrant should be at least 70°C, confirming the absence of a large heat sink. Contrast-enhanced CT

is repeated after treatment to assess completeness of ablation and rule out complications. If inadequately treated areas are identified, the radiofrequency probe is repositioned and the treatment is repeated in a similar fashion. Depending on the manufacturer, the probe tract is ablated during probe withdrawal. For ablation of larger lesions, some authors have described the use of nonconducting temperature probes placed at the peripheral and deep margins of the tumor for active temperature monitoring (Carey and Leveillee, 2007). Rather than multitined probes, multiple individual probes also can be used in overlapping ablations (Karam et al, 2011). Patients who undergo percutaneous CA or RFA under general anesthesia or conscious sedation are discharged in a same-day fashion, whereas those with significant comorbidities or complication typically are admitted overnight.

TREATMENT SUCCESS AND FOLLOW-UP PROTOCOL AFTER TUMOR ABLATION

Interpretation of treatment success after renal tumor ablation had been a controversial subject but with maturing experience and standardization of follow-up protocols, radiographic cross-sectional imaging alone is now the accepted measure of treatment efficacy (Matin et al, 2006). Routine postablative biopsy may serve a role in corroborating radiographic findings. However, the interpretation of biopsy findings after ablation is highly contentious and the overall utility of biopsy in this setting is unresolved. When enhancement and involution are incongruent or recurrence is suspected, multisite-directed core biopsies are appropriate.

Radiographic Interpretation of Success

No pathologic margins are rendered with in-situ ablation; therefore imaging characteristics serve as a surrogate marker of treatment efficacy. In general, the complete loss of contrast enhancement on follow-up CT or MRI is considered evidence of complete tissue destruction and attendant treatment success (Matsumoto et al, 2004; McAchran et al, 2005). At most centers, the first postablation CT or MRI image is obtained at 4 to 12 weeks. If persistent enhancement is identified in any portion of the treated lesion on initial imaging, it is classified as an incomplete ablation and repeat ablation is scheduled (Fig. 62-3). Conversely, if a lesion

demonstrates an initial complete loss of contrast enhancement and later demonstrates enlargement of the lesion and/or contrast enhancement, this is considered local tumor recurrence or progression (Matin, 2010).

In addition to contrast-related characteristics, lesions that undergo CA or RFA demonstrate characteristic but strikingly different appearances on follow-up imaging. The majority of lesions treated with CA demonstrate a greater than 50% reduction in size in the first year after treatment (Deane and Clayman, 2006; Kawamoto et al, 2009). This contraction is due to cellular breakdown and phagocytosis. Conversely, lesions treated with RFA often demonstrate minimal postablative contraction and have a distinctive fibrotic halo or circular demarcation around the treatment zone when performed percutaneously (see Fig. 62-2C), representing a foreign-body giant cell fibrotic response (Park et al, 2006b). Enlargement of a lesion, regardless of the treatment modality or the enhancement characteristics, should be considered a tumor recurrence and biopsy and/or treatment (observation vs. repeat ablation vs. extirpative surgery) should be strongly considered.

Recommended Radiographic Follow-Up Protocol

The AUA guidelines for the follow-up of an ablated renal tumor recommend that CT or MRI with intravenous contrast should be performed at 3 and 6 months after ablation and then annually thereafter for 5 years (Donat et al, 2013). There are no available data suggesting the superiority of MRI or CT in routine follow-up, although some experts contend that CT better distinguishes tumor margins and enhancement in the evaluation of renal tumors (Cadeddu, 2008). Ultrasonography should not be routinely employed to evaluate lesions after ablation unless specific protocols are in place for contrast-enhanced ultrasonography.

Role of Preablation and Postablation Biopsy

To establish a diagnosis and provide uniformity and improved outcomes-based data, the AUA Small Renal Mass and the Follow-up for Clinically Localized Renal Neoplasms Guidelines Panels recently recommended that tumor biopsy be universally performed at or before the time of ablation (Novick et al, 2009; Donat et al, 2013). The diagnostic accuracy in specimen interpretation is high (Schmidbauer et al, 2008) and will help define the frequency of

Figure 62-3. Incomplete ablation with radiofrequency ablation. A, Six-week follow-up computed tomography scan shows contrast enhancement of a left renal cell carcinoma indicative of an incomplete ablation (arrowheads). B, After repeat ablation, the tumor shows no further enhancement on subsequent 6-week follow-up.

postablation follow-up. Conversely, one of the chief criticisms of in-situ renal ablation has been the inability to render definitive pathologic evidence of treatment success. Efficacy with ablative technologies is therefore predicated solely on indirect radiographic interpretation, as previously discussed. The role of a routine postablation biopsy is controversial, and studies have yielded conflicting data on its utility (Matlaga et al, 2002; Lin et al, 2004; Klingler et al, 2007; Raman et al, 2008a; Weight et al, 2008). Considering the dual limitations of imaging studies and biopsy findings, a recent multi-institutional study on the incidence and patterns of recurrence after energy ablative therapy concluded that radiographic detection of residual or recurrent disease was the current state of the art when performed correctly (Matin, 2010).

The controversy surrounding the oncologic accuracy of routine postablation biopsy centers on the histologic interpretation, inherent sampling error, and poor correlation with long-term oncologic results. Much of the debate during the last decade focused on the utility of radiographic imaging alone and the need for postablation biopsy in patients who underwent RFA. In the largest study addressing this controversy, Weight and colleagues (2008) attempted to correlate the radiographic appearance of ablated renal masses with pathologic outcomes. The group examined a total of 109 renal lesions in 88 patients who underwent percutaneous RFA and 192 lesions in 176 patients who underwent laparoscopic CA. At 6 months after treatment, radiographic success (no evidence of contrast enhancement) was noted in 90% of patients who underwent CA and in 85% of patients who underwent RFA. Biopsy at 6 months was then performed in 134 lesions (45%). Pathologic evidence of success was 93.8% with CA and only 64.8% with RFA. Of note, 6 of the 13 patients who underwent RFA and demonstrated viable residual tumor on follow-up biopsy demonstrated no contrast enhancement on follow-up imaging. Conversely, all CA patients who had residual tumor on follow-up biopsy demonstrated definitive contrast enhancement. The authors concluded that radiographic imaging results after CA correlated well with pathologic results, whereas a poor correlation was noted between radiographic imaging and pathologic results after RFA. Routine biopsy after RFA was advocated by the authors.

The study by Weight and colleagues (2008) generated significant debate regarding the efficacy of RFA and need for postablation biopsy, but it was subsequently criticized for selection bias and possible errors in histologic interpretation. Most importantly, the authors used standard hematoxylin and eosin (H&E) staining, which can be misleading after RFA, because cellular architecture is largely preserved despite cell death (Margulis et al, 2004). The duration of this “architectural preservation” has not been defined but is likely 6 months or more. Stern and colleagues (2008) performed tumor biopsy on 20 radiographically negative lesions at least 1 year after RFA and found no evidence of tumor with routine H&E staining. The authors concluded that RFA imparts definitive cellular necrosis and radiographic imaging results correlate well with histopathologic findings at 1 year. To assess shorter term ablation success, cell viability stains, primarily reduced nicotinamide adenine dinucleotide (NADH) diaphorase, have been proposed as a more accurate method of determining cell death after tumor ablation. Marcovich and coworkers (2003) performed a porcine study in which renal tumors were treated with RFA and later resected and examined histologically. Tumor architecture was variably preserved on H&E staining (as discussed), but no NADH diaphorase staining was noted (implying complete cell death). Clinically, Davenport and colleagues (2009) reported on 28 tumors ablated with RFA that had no radiographic evidence of disease. A biopsy sample at 2 months was analyzed using H&E and NADH staining. No viable tumor was identified, confirming the experience of Stern and colleagues (2008).

ONCOLOGIC OUTCOMES

CA and RFA are relatively new compared to extirpative procedures, and thus long-term results are just now being described. Based on

KEY POINTS: FOLLOW-UP AFTER TUMOR ABLATION

- Complete loss of contrast enhancement on follow-up CT or MRI is considered evidence of complete tissue destruction and treatment success.
- The majority of lesions treated with CA demonstrate a greater than 50% reduction in size in the first year after treatment. Lesions treated with RFA demonstrate minimal postablative contraction and have a distinctive fibrotic halo or circular demarcation around the treatment zone. Enlargement of a lesion, regardless of the treatment modality or the enhancement characteristics, should be construed as an ominous sign of local tumor recurrence.
- The AUA Guidelines Panel recommends that a pretreatment tumor biopsy be universally performed before or at the time of ablation.
- The same Guidelines Panel recommends that a CT or MRI scan with intravenous contrast should be performed at 3 and 6 months after ablation and then annually thereafter for 5 years.

these results, the indications for these minimally invasive ablative techniques are rapidly evolving. Therefore the AUA has recently recognized ablative therapies as a treatment alternative for small renal masses in a select group of patients (Novick et al, 2009). Specifically, the role of ablation was noted for patients with primarily T1a (<4 cm) tumors who have risk factors that may increase surgical morbidity. In addition, based on the success of ablation, the AUA Guidelines also now recommend that CA and RFA be discussed with healthy patients as an alternative to partial or radical nephrectomy, with an understanding that tumor recurrence may be more likely and that surgical salvage may be difficult.

Several confounding variables in the literature complicate the interpretation of oncologic success after thermal ablation, including small cohort sizes, short follow-up, inclusion of patients with benign masses, lack of preablation biopsy, inclusion of patients with confounding features for RCC recurrence such as hereditary cancer syndromes, use of various (and evolving) technologies, and variable definitions of recurrence. Fortunately, as the ablative literature continues to mature, the quality of evidence has continued to improve, with most series now controlling for some of these variables. Tables 62-1 and 62-2 summarize RCC-specific outcomes for RFA and CA, respectively, in select series with intermediate- to long-term follow-up. For RFA, local recurrence-free outcomes range between 88% and 92% and corresponding rates for CA are 80% to approximately 86%. Metastasis-free survival and CSS exceed 90% in virtually all series. Although a direct comparison between ablation and partial nephrectomy is limited by patient, tumor, and surgeon selection biases, as well as inconsistent definitions of postablation recurrence, data to date suggest that progression-free survival and disease-specific survival are similar for energy ablative therapy and extirpative therapy in the intermediate term, exceeding 90% in each case. In a head-to-head comparison of RFA and partial nephrectomy in patients with sporadic unilateral T1a RCC, 5-year actual local recurrence-free survival, overall disease-free survival, and progression-free survival were statistically similar between cohorts when including patients who may have required a second ablation for incomplete primary treatment (Olweny et al, 2012). Similar studies to date comparing oncologic outcomes for CA and partial nephrectomy in matched cohorts are limited by inclusion of patients with benign histologic findings, rendering interpretation of recurrence outcomes inconclusive (Klatte et al, 2011; Guillotreau et al, 2012; Whitson et al, 2012). A review of many of these studies follows.

Local Recurrence-Free Survival

The definition of local recurrence-free survival is likely the most contested point with regard to comparing CA, RFA, and partial

nephrectomy. In addition to varying time points for defining success ranging from days to months, surgical approach may confound initial success rates. In particular, compared to partial nephrectomy and cryotherapy, which has been generally reported in the literature using either an open or laparoscopic technique, the majority of RFA cases are performed percutaneously. Because percutaneous treatments are considered to be easily repeatable, physicians performing the procedure may be less aggressive with their initial treatment compared to those approaching a malignancy in an open or laparoscopic fashion. Surgeons performing percutaneous ablation, therefore, may be more accepting of persistent disease on short-term follow-up, presuming that the tumor may be completely ablated with a second, minimally invasive procedure. Indeed, several studies have demonstrated similar recurrence-free survival rates between CA and RFA when taking into account the percutaneous versus laparoscopic approach (Matin et al, 2006; Permpongkosol et al, 2006). Conversely, others comparing laparoscopic and percutaneous ablation have demonstrated inferior initial treatment outcomes with the percutaneous approach compared to the laparoscopic approach but without any difference in CSS or recurrence-free survival (Derweesh et al, 2008; Hui et al, 2008; Malcolm et al, 2009).

Several meta-analyses have evaluated the risk for local tumor recurrence after CA and RFA (Kunkle et al, 2008; Novick et al, 2009; El Dib et al, 2012). For these studies, local recurrence was most often defined as any evidence of residual disease remaining in the treated kidney after the primary ablation procedure. Using this definition, the AUA Guidelines Panel examined 10 studies of CA and 10 studies of RFA and determined a local recurrence-free survival of 90.6% (83.8% to 94.7%) for CA and 87.0% (83.2% to 90%) for RFA (Novick et al, 2009). When compared to alternative extirpative treatments, both CA and RFA demonstrated significantly higher rates of local recurrence despite a shorter overall duration of follow-up, with no significant difference in local recurrence-free survival between CA and RFA and no difference in metastasis-free survival or CSS between ablation and surgical excision. Similarly in a more recent meta-analysis, El Dib and associates (2012) reviewed 31 case series (20 CA, 11 RFA) and found no difference in the clinical efficacy (89% vs. 90%) between CA and RFA, respectively.

Several authors sought to compare the two ablation methods to one another as well as to extirpative surgery. Kunkle and colleagues (2008), using less stringent inclusion criteria than the previously mentioned study by El Dib and associates (2012), performed a meta-analysis comparing outcomes with partial nephrectomy, CA, RFA, and active surveillance, including 40 studies and 936 tumors undergoing ablation. The relative risk for local recurrence was significantly higher with CA (relative risk [RR] 7.45) and RFA (RR 18.23), respectively, when compared to partial nephrectomy, although there was no difference in metastasis-free survival among any approaches. A follow-up study by the same authors, in which 77% of CA cases were performed open or laparoscopically compared to just 6% of RFA cases, reported a local tumor progression of 5.2% after CA and 12.9% after RFA. Again, there was no significant difference in the incidence of metastases associated with any of the tested variables by univariate or multivariate regression analyses, including ablation modality. A recent cohort study using data from the SEER registry found that patients undergoing nephron-sparing surgery had a 5-year disease-specific survival that was improved by 1.7% over ablation (Whitson et al, 2012). However, there was no significant difference in the risk for death when comparing the two ablative technologies. Interestingly, the authors noted that the difference in disease-specific survival between nephron-sparing surgery and ablation has decreased over time, possibly indicating improved outcomes from ablative procedures as a result of increased experience, improved patient selection, and technical modifications.

In addition to surgical factors and their influence on outcomes after ablative procedures, long-term follow-up data suggest that tumor size is a significant indicator of ablation success. Best and associates (2012) found that the 5-year overall

local recurrence-free survival in 108 biopsy-proved RCCs was 95% for those with tumors smaller than 3 cm, but only 78% for those with tumors 3 cm or larger ($P = .002$). Similarly, Psutka and colleagues (2013) demonstrated a 5-year local recurrence-free survival and overall disease-free survival of 96.1% and 91.5% with tumors smaller than 4 cm (T1a) compared with 91.9% and 74.5% in a comparative group of 42 patients with tumors larger than 4 cm (T1b). With regard to CA, Tanagho and colleagues (2012) demonstrated a 6-year overall disease-free survival of 80%, with tumor size 2.6 cm or greater found to be the only significant predictor of oncologic failure on multivariate analysis.

Metastatic Recurrence-Free Survival

For the purpose of evaluating metastasis-free survival, the AUA Guidelines Panel defined metastatic recurrence as any disease present in the body other than in the treated kidney or associated renal fossa after primary treatment. Based on this definition, mean metastatic recurrence-free survival was 95.3% (91.1% to 97.5%) for CA and 97.5% (94.8% to 98.8%) for RFA (Novick et al, 2009). There was no significant difference in metastatic recurrence-free survival between tumor ablation and extirpative treatments, including laparoscopic and open partial and radical nephrectomy. Importantly, ablative procedures had the shortest follow-up, underscoring the need for more long-term follow-up of patients undergoing thermal ablation.

As seen in Tables 62-1 and 62-2, over the last several years, multiple centers have reported on their intermediate- to long-term outcomes, including multiple series with more than 5 years of follow-up for RFA (Tracy et al, 2010; Zagoria et al, 2011; Best et al, 2012; Olweny et al, 2012; Psutka et al, 2013) and CA (Aron et al, 2010; Tanagho et al, 2012). Although the presence of confounding factors precludes meaningful comparisons among these studies, these data seem to support the fact that outcomes for ablative procedures are durable beyond 5 years and up to 10 years.

Cancer-Specific Survival

The AUA meta-analysis published in 2009 evaluated the risk for dying from RCC after CA or RFA and concluded that CSS was 95.2% (89.2% to 97.9%) with CA and 98.1% (95.2% to 99.2%) with RFA. CSS was significantly higher with laparoscopic partial nephrectomy than for CA, but there was no significant difference in CSS between laparoscopic partial nephrectomy and RFA. There also was no significant difference in CSS between CA and RFA. Again, selection bias and short duration of follow-up may confound these results. More recent publications reporting on long-term outcomes have verified a CSS ranging from 78% to 100% for CA (Aron et al, 2010; Tanagho et al, 2012) and approximately 98% for RFA (Zagoria et al, 2011; Olweny et al, 2012; Psutka et al, 2013).

Overall Survival

Patients undergoing ablative procedures tend to be older and have more comorbidities than those undergoing extirpative surgery (Novick et al, 2009). Thus the mean overall survival rate after ablative procedures is typically 75% to 85% at 5 years (Tracy et al, 2010; Zagoria et al, 2011; Psutka et al, 2013). The higher overall survival rates previously published by the AUA Guidelines Panel for CA (95.8%) and RFA (93.7%) likely reflect the shorter follow-up of studies used in their analysis. There does not appear to be any significant difference in overall survival between CA and RFA. Interestingly, the Guidelines Panel did find a higher overall survival for patients undergoing open partial nephrectomy than radical nephrectomy, which may be related to a deleterious effect of chronic kidney disease associated with open radical nephrectomy (Tan et al, 2012). As ablative procedures have shown similar, if not improved, renal function when compared to partial nephrectomy, long-term data in younger cohorts may show a potential overall improved survival rate for ablation compared to radical nephrectomy (Faddegon et al, 2013).

Cryoablation versus Radiofrequency Ablation

Any debate regarding the superiority of CA versus RFA is subject to the same faults, confounders, and ambiguities as the aforementioned comparisons between in-situ tumor ablation and extirpation. Beyond issues of ill-defined radiologic and pathologic end points, there is considerable variability in patient selection, tumor size and location, technique, and approach (laparoscopic vs. percutaneous), as well as inherent bias for a particular ablative modality. To date, there are no data that directly compare percutaneous and laparoscopic CA to its respective RFA counterparts.

Two large single-institution studies with significant experience with both CA and RFA have reported comparable oncologic outcomes, impact on renal function, and complication rates. In 2006, [Hegarty and colleagues](#) compared outcomes in a somewhat disparate cohort of 164 laparoscopic CA procedures and 82 percutaneous RFA procedures. Although there was no significant difference in tumor size between the two groups, the RFA cohort contained more patients with central tumors and tumors in solitary kidneys, which likely accounted for the higher radiographic evidence of disease persistence or recurrence noted in patients who underwent percutaneous RFA (11% vs. 2% for laparoscopic CA). Importantly, there was no significant impact on renal function with either modality and the short-term CSS for CA and RFA were comparable at 98% and 100%, respectively. Recently, [Atwell and associates \(2013\)](#) reported their single-institution contemporary outcomes comparing percutaneous ablation with either RFA or CA. Overall, in their experience with 445 tumors 3 cm or smaller over a 10-year period (256 RFA, 189 CA), the local tumor recurrence rate was 3.2% for RFA at a mean of 2.8 years and 2.8% for CA at a mean of 0.9 year. In patients with biopsy-proved RCC, there was no difference in local recurrence-free survival at 1 (100% vs. 97.3%), 3 (98.1% vs. 90.6%), and 5 years (98.1% vs. 90.6%), when comparing RFA and CA, respectively.

Ultimately, the result of these three recent meta-analyses offer the most insight into the comparative oncologic merit and potential limitations of CA and RFA ([Kunkle and Uzzo, 2008](#); [Novick et al, 2009](#); [El Dib et al, 2012](#)). It appears that there is no significant difference in the risk for local tumor recurrence, disease progression/metastasis, CSS, and overall survival between CA and RFA.

Laparoscopic versus Percutaneous Renal Tumor Ablation

One limitation when comparing series of renal tumor ablation to each other is the variability in technique. The assumption that the success of a laparoscopic and percutaneous ablation is comparable remains debatable. Indeed, until recently the vast majority of CA procedures were approached laparoscopically, whereas more than 95% of RFA procedures are performed percutaneously. [Crouzet and colleagues \(2009\)](#) retrospectively compared similar cohorts of 244 laparoscopic renal CA procedures with 63 percutaneous renal CA procedures. There was no significant difference in renal functional outcomes between the two groups, and patients undergoing percutaneous ablation had a shorter length of stay. With a minimum follow-up of 2 years, the percutaneous cohort demonstrated a higher incomplete treatment rate and need for re-treatment; however, there was no difference in overall survival, CSS, and recurrence-free survival between the two groups. Similar studies comparing laparoscopic and percutaneous tumor ablation have confirmed these findings for both RFA and CA ([O'Malley et al, 2006](#); [Derweesh et al, 2008](#); [Hinshaw et al, 2008](#); [Hui et al, 2008](#); [Malcolm et al, 2009](#)).

In comparison to these studies, [Finley and colleagues \(2008\)](#) reported their 4-year experience with laparoscopic and percutaneous renal CA in 37 patients with 43 tumors. Operative time and duration of hospitalization were significantly shorter with the percutaneous approach, but there was no significant difference in the number of incomplete ablations. Similarly, [Leveillee and colleagues \(2013\)](#) reported their experience with laparoscopic and percutaneous RFA in 274 patients with 292 tumors. The radiographic recurrence rate for either approach was only 4%.

KEY POINTS: ONCOLOGIC OUTCOMES

- The interpretation of oncologic outcomes after renal tumor ablation is challenging and subject to confounding variables such as the inclusion of nonmalignant tumors.
- When compared to alternative extirpative treatments, both CA and RFA demonstrate significantly higher rates of local recurrence, albeit they can be salvaged with repeat ablation or surgery.
- There is no apparent significant difference in metastatic recurrence-free survival when comparing RFA and CA to each other or against extirpative treatments.
- Any discussion of oncologic efficacy regarding ablative technologies must focus on long-term markers of success, such as metastasis-free survival, CSS, renal function preservation, and quality-of-life outcomes.

COMPLICATIONS

As part of the recently published small renal mass guidelines from the AUA, a meta-analysis comparing urologic and nonurologic complications after CA, RFA, and alternative extirpative approaches was performed ([Novick et al, 2009](#)). The incidence of major urologic complications with renal CA and RFA was 4.9% (range 3.3% to 7.4%) and 6.0% (4.3% to 8.2%), respectively. Major nonurologic problems occurred in 5% (3.5% to 7.2%) of patients undergoing CA and 4.5% (3.2% to 6.2%) of those undergoing RFA. The risk for major urologic complications was lower with ablative techniques than with either laparoscopic or open partial nephrectomy. There was no significant difference in urologic complications with CA versus RFA.

The majority of complications that occur with renal ablation are minor, with major complications occurring in as few as 2% of cases ([Johnson et al, 2004](#)). However, up to 20% of complications may require hospital readmission, procedural intervention, or transfusion ([Johnson et al, 2004](#)). Laparoscopic ablation tends to have a higher rate of complications than percutaneous ablation, with an estimated one third of laparoscopic ablation complications occurring as a result of laparoscopic technique ([Johnson et al, 2004](#)). Complications decrease significantly, regardless of surgical approach, with increasing operative experience.

To objectively determine the risk for complications, several authors reported on the use of standardized scoring systems for determining complication severity as well as the risk for complications. Several studies on extirpative surgery for renal malignancy have demonstrated that the RENAL nephrometry score ([Kutikov and Uzzo, 2009](#)) can predict both surgeon preference and postoperative complications ([Canter et al, 2011](#); [Rosevear et al, 2012](#)). Accordingly, in a retrospective review of 77 laparoscopic CAs performed at three high-volume centers, [Okhunov and colleagues \(2012\)](#) reported their complication rates based on low (4 to 6), moderate (7 to 19) or high (10 to 12) nephrometry scores. Overall, their cohort had a complication rate of 19.5%, including 9.5% with major complications. There was a significant association with tumor complexity and complications, with no complications in the low complexity cohort compared to 35% and 100% of those with moderate or high nephrometry scores, respectively. Similarly, [Schmit and colleagues \(2013\)](#) reported their extensive experience with 679 percutaneous tumor ablations, stratifying patients by renal complexity based on nephrometry score to predict outcomes and complications of percutaneous ablation (both CA and RFA). In their series, 5.6% of patients developed major complications, as graded by the Clavien-Dindo classification system ([Dindo et al, 2004](#)), including 7.8% of CAs and 2.7% of RFAs. Patients with complications had a higher mean nephrometry score than those who did not experience complications (8.1 vs. 6.8). Patients with high-complexity tumors (nephrometry score 10 to 12) had a risk of 14.3% for major complications. Although there was a clear difference between complications with regard to ablative technology (CA

vs. RFA), the results were difficult to compare because the authors typically performed CA on larger, more complex lesions and RFA on more exophytic and smaller lesions. A subsequent report from our institution examining only RFA (both percutaneous and laparoscopic) indicated an overall complication rate of 7.5%, with major complication rate of 2% (Seidman et al, 2013). Overall there was no significant difference in postoperative complications based on nephrometry complexity in this group of RFA-only patients.

The most common complication after renal tumor ablation is pain or paresthesia at the percutaneous probe insertion site, occurring in up to 8% of patients (Farrell et al, 2003b). The current generation of cryoprobes comes with thermal insulation along the shaft, which has led to a decrease in freezer burns as were seen with prior generations. The active portion of the RFA probe is only along the most distal aspect. However, with RFA, to prevent inadvertent nerve damage, tract ablation should be performed only long enough to remove the probe from the kidney and surrounding the Gerota fascia. Electrical skin burns after RFA, which may occur at the site of the grounding pads, should be incredibly rare and can be avoided by placing the pads at the exact same level on the patient's posterior thigh (McDougal et al, 2005). Because energy returning to the generator travels in the shortest arc, the pads should be placed perpendicular to the long axis of the thigh to increase surface area for energy dissipation.

Complications from damage to surrounding intra-abdominal organs can be minimized through appropriate patient selection, preoperative planning, and good surgical technique. Cross-sectional preoperative imaging is essential to determine if a tumor should be managed with a laparoscopic or percutaneous approach. For patients in whom there may be a concern regarding adjacent organs, additional imaging can be obtained with the patient in various positions to plan an appropriate needle path. Patients with anterior tumors, tumors close to the collecting system, or without a suitable access tract on preoperative imaging, should be scheduled for laparoscopic ablation or have consideration for displacement of organs using intraprocedural hydrodissection. **Ideal patients for percutaneous treatment are those with posterior tumors, those with tumors located more than 0.5 cm from the ureteropelvic junction or renal pelvis, and those with tumors at least 1 cm from surrounding bowel.**

Urothelial damage may manifest as minor hematuria, hematuria with significant clots, or urinary tract obstruction. Patients with hematuria should be managed conservatively, unless they present with significant hemorrhage, at which time they can be managed with selective angioembolization. There have been several reports of urinary fistula or collecting system injury after RFA as well as CA (Gervais et al, 2005a, 2005b; Janzen et al, 2005; Brown and Bhayani, 2007). **Permanent urothelial damage may manifest as either calyceal obstruction or ureteral obstruction if damage occurs at the ureteropelvic junction or distally (Johnson et al, 2003).** In extreme cases, damage to the urinary tract may result in perirenal urinoma formation or cutaneous urinary fistula. Patients with ureteral obstruction or urine leakage from the collecting system may be managed conservatively or with insertion of an indwelling ureteral stent (Fig. 62-4). Patients with significant urinoma accumulation should have a percutaneous drain placed.

Injury to the pleural cavity resulting in pneumothorax or hemothorax can occur if probes are placed above the twelfth rib to treat upper pole lesions. These complications are typically recognized either during the procedure as breathing difficulties or, with percutaneous access, on routine imaging during tumor treatment. If a simple pneumothorax is identified, it may be treated by aspiration using a small needle inserted into the pleural space at the conclusion of the case. In the absence of a large or persistent pneumothorax, placement of a chest tube should be performed sparingly. Postoperatively, chest pain or shortness of breath should trigger suspicion of pneumothorax and prompt performance of an upright chest radiograph.

Colon injury after renal mass ablation is exceedingly rare and should be largely preventable with appropriate surgical technique. During percutaneous access, tumors within close proximity to

bowel may be dissected free from the treatment area by injecting saline to hydrodissect tissues and develop a safe working space around the tumor (Farrell et al, 2003a; Clark et al, 2006; Lee et al, 2006) (Fig. 62-5). However, reproducibility and surgeon familiarity with the patient's anatomy may make these lesions more suitable for the laparoscopic approach by which the bowel can be safely removed from the operative field. Patients with colon damage should be managed along with a general surgical consultation. Patients with a controlled colon-nephric fistula should be initially managed with placement of a ureteral stent, whereas those with a persistent fistula or with colon-cutaneous fistulas may require surgical diversion or a trial of total peripheral nutrition (Vanderbrink et al, 2007). Patients with frank colon perforation and signs of peritonitis should be managed with prompt surgical exploration.

When treating posterior tumors percutaneously, damage to the nerves running along the posterior abdominal wall can lead to self-limiting neuralgia or neuroapraxias (Lee et al, 2006; Baker, 2007). This complication can be avoided by positioning the patient so that the tumor falls away from the body wall or by hydrodissecting the plane between kidney and body wall (Lee et al, 2006). For patients with multiple posterior tumors or with limited perinephric fat between the kidney and body wall, strong consideration should be given to the laparoscopic approach, in which the kidney can be physically relocated away from the body wall.

Intraoperative or postoperative hemorrhage may occur in up to 11% to 27% of patients undergoing ablative renal procedures (Finley et al, 2008), with transfusion rates of 3.2% (2% to 4.9%) with CA and 2.4% (1.4% to 4%) with RFA (Novick et al, 2009). **The primary risk factor for hemorrhage is the use of multiple probes for treatment of larger renal masses (Lehman et al, 2008).** To decrease the risk for tumor fracture during CA, probes should be given adequate time to thaw, because premature removal increases the risk for tumor fracture and hemorrhage. Bleeding during needle placement may be controlled by proceeding with the ablation, especially with the coagulative nature of RFA. Bleeding during laparoscopic ablation can be managed with the use of hemostatic agents combined with direct pressure. If bleeding continues after ablation, consideration should be given to selective angioembolization. As with any percutaneous needle placement, percutaneous ablation risks damage to the abdominal wall vasculature, and thus care should be taken to avoid intercostal arteries. When injury does occur, it is typically visualized during the procedure with routine imaging. The expanding hematoma may be observed with serial imaging (if rapidly expanding) or serial hematocrit levels (if stable), with only the rare case requiring angiographic embolization.

Postoperative infection after tumor ablation, in the absence of a large hematoma or urinoma, is exceedingly rare, but may be lethal (Schmit et al, 2013). Patients at risk for infection are those with chronic colonization of the urinary tract (e.g., ileal conduit) or active infection at the time of procedure (Bandi et al, 2007; Brown and Bhayani, 2007). When infectious complications do occur, they typically manifest from 1 to 6 months later as a chronic drainage or retroperitoneal abscess. Patients at risk for urinary tract infection (UTI) should be screened by urine culture and treated appropriately before their ablation procedure. Whereas we routinely administer perioperative prophylactic antibiotics at the time of the surgery, some authors suggest broad-spectrum coverage 2 days before and 2 weeks after surgery for patients at high risk for infection (Wah et al, 2008).

NEW ABLATION MODALITIES

High-Intensity Focused Ultrasonography

As an acoustic wave is propagated through tissue, a portion of its energy is absorbed and converted into heat (Madersbacher et al, 1995; Vricella et al, 2009). When the ultrasound waves are focused with an appropriately shaped transducer the temperature at the focal point can exceed the threshold for cell death, while adjacent tissue is spared. At sufficiently high intensities ($>3500 \text{ W/cm}^3$),

Figure 62-4. Urine leak after percutaneous radiofrequency ablation (RFA). **A**, Preoperative imaging shows 2.5-cm endophytic left renal mass (*arrow*). **B**, Immediate postoperative image after ablation shows urinary extravasation at the site of RFA. **C**, Postoperative day 1 computed tomography (CT) image shows no change in the fluid collection. **D**, Three-year follow-up CT shows involution of the treated area with postoperative halo.

KEY POINTS: COMPLICATIONS FOLLOWING TUMOR ABLATION

- The risk for major urologic complications is lower with ablative techniques (~5%) than with either laparoscopic or open partial nephrectomy. There is no significant difference in urologic complications between CA and RFA.
- For CA, postoperative hemorrhage is the most commonly cited major adverse risk.
- Bleeding is less common with RFA than CA and may be ideally suited for those at risk for postoperative hemorrhage.
- The risk for complications with CA may be predicted by nephrometry score, whereas the same may not hold true for RFA.
- Commonly cited minor complications with CA and RFA include pain and paresthesia at the probe insertion site, UTIs, damage to surrounding structures, and self-limited hematuria.

cavitation and microbubble formation occur that yield extremely high temperatures and a mechanically disrupting “shock wave” effect similar to that seen with extracorporeal shock wave lithotripsy (Kieran et al, 2007). Termed high-intensity focused ultrasound (HIFU), it is a unique thermal ablation technology in that it can be administered in an entirely noninvasive, extracorporeal fashion minimizing or eliminating the risk for tumor seeding, hemorrhage, or urinary extravasation.

HIFU employs a transducer that is used for treatment and monitoring. Under real-time guidance, the HIFU beam is focused on the treatment zone and a defined area is ablated. The transducer is then refocused to ablate overlapping volumes and “paint” a larger overall volume of tissue. Treatment times can be lengthy, with a mean reported duration of nearly 5.5 hours (1.5 to 9 hours) (Köhrmann et al, 2002; Marberger et al, 2005; Häcker et al, 2006). A myriad of parameters, including focal length, type of transducer employed, and type of treatment system have been investigated and are beyond the scope of this chapter.

Although early clinical trials have established the feasibility of transcutaneous HIFU, based on the data available and the existing

Figure 62-5. Intraoperative hydrodissection for anterior tumor. **A**, Preoperative imaging shows a 3-cm anterior renal mass. **B**, Intraoperative imaging demonstrates large bowel anterior to the lesion. **C**, D5 + contrast is injected percutaneously to hydrodissect bowel and create a window for placement of two cryoprobes (arrow). **D**, Ice ball is demonstrated by hypodense lesion adjacent to the cryoprobes (arrowheads). (Courtesy Fred Lee Jr, MD, University of Wisconsin.)

clinical hurdles, it should be considered only investigational at this time. Two important ablate-and-resect studies have noted incomplete treatment in all specimens, highlighting the challenge of accurate targeting. Vallancien and colleagues (1993) performed transcutaneous HIFU in eight patients, with approximately 10% of the cohort exhibiting skin burns and all specimens demonstrating pathologic evidence of viable tumor. Similarly, Marberger and colleagues (2005) treated 18 renal units with HIFU, and incomplete ablation was noted in all cases at surgery. Ritchie and colleagues (2010) reported a very limited experience with transcutaneous HIFU ablation and subsequent intermediate-term radiographic follow-up. MRI 2 weeks after treatment suggested viable tumor in 8 of 15 treated tumors. Of 14 patients with at least 6 months' follow-up, 10 appeared to have tumor involution with loss of enhancement and shrinkage (mean follow-up 36 months). Purported explanations for these collective incomplete treatments have included poor targeting secondary to respiratory movement and acoustic interference (acoustic shadowing, reverberation, and refraction) and lack of effective intraoperative monitoring of treatment progress. To circumvent these issues, laparoscopic HIFU has been investigated, and though results are favorable its viability as a treatment modality is questionable because it would compete with established laparoscopic CA and RFA techniques (Klingler et al, 2008). In summary, outcomes with renal HIFU have proved inferior to alternative ablative technologies and its use in this regard should be considered investigational.

Radiation Therapy

Historically, radiation therapy was considered ineffective in the treatment of RCC. It remains unclear whether poor outcomes with radiation therapy for RCC are due to an inherent resistance to radiation or to limitations with radiation delivery (Camphausen and Coia, 2008). There are many technical challenges associated with treatment of kidney tumors, including limited radiation tolerance of the normal parenchyma, significant scatter with attendant damage to the surrounding tissues, and difficulty of target localization. Furthermore, conventional external-beam radiation systems are inadequately designed to deliver high doses in a focal manner.

Stereotactic ablative body radiation (SABR) is an emerging treatment paradigm defined by the American Society of Therapeutic Radiology and Oncology as a "treatment method to deliver a high dose of radiation to the target, using either a single dose or a small number of fractions with a high degree of precision within the body" (Potters et al, 2010). As opposed to conventional radiation delivery techniques, modern stereotactic treatment systems employ three-dimensional coordinates to target and compensate for respiratory movement and radiation scatter by automatically tracking, detecting, and correcting for tumor and/or organ movement without interrupting the treatment or repositioning the patient. This tracking system is image guided and dependent on a constant reference point (e.g., fiducial marker) that is continually recognized by the linear accelerator. High-dose radiation beams move in real time

with the respiratory cycle and are therefore extremely accurate (Ponsky et al, 2007). Not only is radiation scatter minimized, but higher doses may be applied in a focal manner that effectively ablates masses in the kidney without compromising overall renal function. Ponsky and colleagues (2003) first evaluated stereotactic radiosurgery in the porcine kidney using the CyberKnife (Accuray, Palo Alto, CA) treatment system. Treatment doses between 24 to 40 Gy resulted in complete necrosis in the treatment zone with no collateral damage to adjacent tissue. Building on this initial animal experience, Ponsky and colleagues (2007) subsequently performed a phase I study on three human patients with a mean renal tumor size of 2 cm. A total of 16 Gy was administered in a fractionated fashion. Patients were followed for 8 weeks, after which a partial nephrectomy was performed. No adverse events or radiation toxicities were noted. Histopathology demonstrated residual RCC in two patients and no evidence of viable tumor in the remaining patient.

Svedman and colleagues (2006) performed a retrospective study evaluating the efficacy and safety of stereotactic radiosurgery in the management of inoperable or metastatic primary RCC. Thirty patients with 82 lesions underwent treatment with varied dose/fractionation schedules. At a median follow-up of 52 months, complete response was noted in 21% of patients, with another 58% demonstrating a partial/stable response.

A critical and systematic review of SABR for primary RCC recently identified 10 studies consisting of 126 patients treated with between one and six fractions (Siva et al, 2012). The most common treatment regimen was 40 Gy over five fractions. Median or mean follow-up ranged from 9 to 57 months. Local control was defined only radiologically and was estimated at 94% at 2 years. The weighted rate of grade 3 or higher adverse effects was only 3.8% with the most common being radiation dermatitis and enteritis.

Certainly, the responsiveness of RCC to stereotactic radiosurgery in the aforementioned trials argues against its radioresistant reputation. Presently its use should be considered experimental because there is no consensus for dose fractionation or technique. With improved treatment protocols and well-designed prospective trials, SABR ultimately may play a significant role in the treatment of RCC.

Microwave Ablation

Microwave ablation (MWA) delivers energy through semiflexible probes that are inserted directly into the target lesion and functions in a similar fashion to RFA. Medical applications of microwave energy operate in the 900-MHz to 2.45-GHz range of the electromagnetic spectrum and create rapid water ion oscillation in the tissue and frictional heat. The degree of tissue penetration and heat produced is related to the water content of the target tissue, which can be more difficult to predict in the heterogeneous kidney parenchyma environment (Rehman et al, 2004; Moore et al, 2010). MWA is capable of achieving treatment temperatures ($>60^{\circ}\text{C}$) with greater rapidity than RFA and is not limited by tissue charring and desiccation as experienced with RFA. These qualities may translate into more efficient treatment times and may make MWA less susceptible to the heat sink phenomenon (Liang and Wang, 2007).

MWA technology was initially designed for the percutaneous treatment of liver tumors and has enjoyed considerable success in this capacity. Its use in the management of renal tumors remains investigational, with no standardized protocols for its use and with only sporadic clinical feasibility studies reported. Clark and colleagues (2007) performed a phase I study in which 10 patients underwent MWA of suspected RCC at the time of radical nephrectomy. When examined pathologically, lesions as large as 5.7 cm \times 4.7 cm \times 3.8 cm were achieved with complete and uniform tissue necrosis. In 2008, Liang and colleagues first reported a percutaneous ablation experience in 12 patients under ultrasound guidance. No significant adverse events were reported, and at a median follow-up of 11 months, no cancer recurrence was noted on imaging. In contradistinction, Castle and colleagues (2011) reported more sobering 38% recurrence rate in 10 patients over an 18-month follow-up period. Most recently, the only direct comparison of MWA to partial

nephrectomy reported comparable 3-year recurrence-free survival of 90% and 97%, respectively (Guan et al, 2012).

At this point, MWA offers considerable promise as an alternative thermal ablative technology. However, larger prospective studies are necessary to better understand the optimal tumor characteristics, risks, and morbidity. At this time it should remain investigational.

Laser Interstitial Thermal Therapy

Laser interstitial thermal therapy (LITT) employs specialized laser fibers to deliver energy directly into tissue. These fibers emit laser light that is converted to heat, achieving tissue necrosis. Thus far, LITT has relied on neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers and diode lasers. Results have been difficult to interpret owing to the small number of treated patients and a lack of clinical follow-up (Williams et al, 2000; Dick et al, 2002; Gettman et al, 2002b). The use of LITT remains investigational.

Irreversible Electroporation

Irreversible electroporation (IRE), is a novel nonthermal method for ablation of living tissue that potentially offers advantages over RFA and CA. Electroporation is a process whereby an electric field applied across cells generates nanoscale pores within cellular membranes that can be either reversible or lethally irreversible depending on the magnitude of electricity applied. IRE is produced through a series of electrical pulses delivered by a single (bipolar) or multiple (monopolar) electrodes. With appropriate modulation it is able to ablate a substantial and reproducible amount of tissue by increasing cell membrane permeability that ultimately leads to cell death (Edd et al, 2006). The result is a nonthermal effect that preserves the extracellular matrix, tissue scaffolding, ductal structures, and large blood vessels (Edd et al, 2006; Deodhar et al, 2011).

Because of the potential to avoid the shortcomings of thermal ablation, there is a great deal of interest in applying IRE to ablation of renal tumors. Although IRE has been shown to be effective in ablating liver and prostate tissue, these results cannot be readily extrapolated to the kidney, which is substantially different given the vigorous arterial blood supply, complex collecting system, and presence of urinary solutes. The efficacy of IRE ablation of renal parenchyma was first described by Tracy and colleagues (2011). When IRE bipolar and monopolar electrodes (Angiodynamics, Queensbury, NY) were used to perform laparoscopic ablations on porcine kidneys, histopathologic evaluation revealed absence of cellular viability immediately after IRE treatment that evolved to diffuse cellular necrosis by 7 days and chronic inflammation, cellular contraction, and fibrosis by day 14. In addition to its effect on the parenchyma, IRE appeared to provide some urothelial sparing with initial ulceration followed by signs of early repair and viability.

Other authors subsequently confirmed these findings using image-guided percutaneous placement of IRE electrodes. Deodhar and associates (2011) used CT-guided placement of monopolar electrodes and reported that the IRE lesions were characterized by nonenhancing hypodense ablation zones immediately after treatment with no identifiable ablation zone by 3 weeks in the majority of animals. Additionally, there were no cases of urinary extravasation or evidence of collecting system injury in any of the cases, confirming the potential connective tissue-sparing effects of IRE.

There is very limited clinical experience with IRE. Pech and coworkers (2011) designed a phase I trial evaluating safety of the technology in six patients with tumors 2.5 to 3.5 cm scheduled for extirpative surgery (partial or radical nephrectomy). Electrodes were placed under ultrasound guidance and delivered using cardiac synchronization. All patients tolerated the procedure well, with no changes identified during the procedure in regard to pulse rate, mean blood pressure, central venous pressure, or changes in ST segment on electrocardiogram. Acutely, 15 minutes after treatment ablated lesions were examined with H&E staining, which showed cellular swelling but was inadequate at assessing postablative cellular viability. In summary, the experience with IRE ablation of

renal tumors is very limited and its use in this regard should be considered investigational.

Targeted Embolization and Ablation

Owing to the heat sink phenomenon with RFA, highly vascular central lesions or lesions positioned adjacent to the renal hilum are often inadequately ablated. Studies estimate treatment failures to be as high as 40%. In an attempt to address conductive heat loss, investigators have performed selective arterial embolization before RFA (Yamakado et al, 2006; Gebauer et al, 2007; Mahnken et al, 2009). Theoretically, selective embolization should allow for more homogeneous heating and improved tissue necrosis. Clinical reports are sporadic and anecdotal. Therefore the use of targeted angioembolization before RFA remains investigational.

KEY POINTS: NEW ABLATION TECHNOLOGIES

- Although there are a number of promising ablation modalities on the horizon, the majority of these should be considered investigational at this time.
- The most promising future ablation modalities appear to be stereotactic radiosurgery, microwave thermotherapy, and IRE. However, significant study is required to further determine their potential benefits compared to the well-established methods of CA and RFA.

CONCLUSIONS

Once considered experimental and appropriate only for patients with significant comorbidities, CA and RFA are currently considered viable alternatives to extirpative management. In-situ ablation confers less treatment-related morbidity than either open or laparoscopic partial nephrectomy and offers comparable renal function preservation compared with partial nephrectomy. CA and RFA are technically less challenging than other nephron-sparing approaches, though learning curves exist for patient selection, tumor targeting, probe deployment, and generator use. Results from recent meta-analyses demonstrate modestly inferior local tumor control compared with partial and radical nephrectomy, but with equivalent cancer-specific and overall survival. Interpretation of treatment

success remains challenging with existing protocols, and long-term follow-up is needed to confirm these findings. No prospective literature currently exists that addresses the superiority of CA or RFA. Ultimately, the decision to treat a small renal mass with an ablative technology should take into account tumor-related characteristics, patient demographics and comorbidities, and the values and desires of the patient.

Prognostic Factors

Surgical Management of Metastatic Renal Cell Carcinoma

Immunologic Approaches in the Management of Advanced Clear Cell Renal Cell Carcinoma

Molecular Basis for Targeted Approaches in Clear Cell Renal Cell Carcinoma

Targeted Molecular Agents in Clear Cell Renal Cell Carcinoma

Systemic Therapy for Non–Clear Cell Variants of Renal Cell Carcinoma

Renal cell carcinoma (RCC) is a term that includes a variety of cancers arising in the kidney and encompasses several histologically, biologically, and clinically distinct entities (Linehan et al, 2007, 2009). An estimated 63,920 new cases of cancer arising in the kidney or renal pelvis were diagnosed in 2014 in the United States (Siegel et al, 2014). Approximately one third of all newly diagnosed RCC patients present with synchronous metastatic disease and an additional 20% to 40% of patients with clinically localized disease at diagnosis will eventually develop metastases (Skinner et al, 1971; Rabinovitch et al, 1994; Bukowski, 1997). Metastatic RCC is almost always fatal, with 10-year survival rates of less than 5% (Bukowski, 1997; Motzer et al, 1999, 2000; Motzer and Russo, 2000; Négrier et al, 2002); patients with metastatic disease account for the majority of deaths (approximately 13,860 a year in the United States) related to RCC (Siegel et al, 2014).

Advances in our understanding of the genetic and molecular changes underlying the individual subtypes of RCC have led to the development of novel agents designed to reverse or modulate aberrant pathways contributing to renal oncogenesis. These “targeted” therapeutic strategies have largely supplanted other treatment modalities in the management of metastatic clear cell kidney cancer; however, surgery, irradiation, and cytokine therapy remain appropriate choices in the management of selected patients with advanced clear cell RCC. More recently, the recognition that agents modulating T-cell function may have activity against a variety of solid tumors, including RCC, has reinvigorated interest in immune-based strategies; the efficacy of several immune “checkpoint” inhibitors in clear cell RCC is currently being evaluated in several phase III studies. Lastly, the advent of techniques that allow comprehensive interrogation of the cancer genome have allowed identification of hitherto unrecognized alterations affecting diverse cellular functions, including carbohydrate and amino acid metabolism as well as chromatin remodeling, in clear cell RCC. Although the precise contribution of these changes in the genesis and progression of kidney cancer remains to be determined, it is hoped that a better understanding of these pathways will spawn additional strategies to combat what remains an incurable group of malignancies.

Although agents effective in clear cell RCC are often used in patients with other subtypes of RCC, there is scant evidence from prospective studies to justify their utility in non–clear cell RCC variants. Elucidation of aberrant oncogenic pathways in papillary, chromophobe, and other variants of RCC has paved the way for evaluation of targeted therapeutic approaches in these histologic subtypes (Linehan et al, 2009).

PROGNOSTIC FACTORS

Patients with metastatic RCC generally have a poor prognosis, with the majority succumbing to their disease. Ten-year survival in patients diagnosed with metastatic disease was estimated to be less than 5% in the era of cytokine therapy and is unlikely to change significantly with the advent of targeted therapy. However, several clinical features, such as a long time interval between initial diagnosis and appearance of metastatic disease and presence of fewer sites of metastatic disease, have been observed to be associated with better outcome. Conversely, poor performance status and the presence of lymph node and/or liver metastases have long been recognized to be associated with shorter survival. Investigators at the Memorial Sloan Kettering Cancer Center (MSKCC) evaluated a variety of clinical and laboratory parameters in 670 patients enrolled in various clinical trials of chemotherapy or immunotherapy from 1975 to 1996 in an effort to identify those pretreatment factors that were able to best predict outcome (Motzer et al, 1999). In a multivariate analysis, a poor performance status (Karnofsky score <80), an elevated serum lactate dehydrogenase level (>1.5 times the upper limit of normal), a low hemoglobin (less than the lower limit of normal), an elevated corrected calcium concentration (>10 g/dL), and lack of prior nephrectomy were independent predictors of a poor outcome (Table 63-1 and Fig. 63-1). Patients could be stratified into three distinct prognostic groups based on these five poor prognostic factors (see Table 63-1). The overall survival (OS) times in patients with no adverse factors (favorable-risk group), one to two risk factors (intermediate-risk group), and more than three risk factors (poor-risk group) were 20 months, 10 months, and 4 months, respectively (Motzer et al, 1999). Subsequently, the same group of investigators identified poor performance status, high serum calcium, low hemoglobin, elevated lactate dehydrogenase, and a short time interval from initial diagnosis to initiation of systemic therapy (<1 year) as factors that could best predict a poor outcome in 463 patients receiving interferon-based therapy in the first-line setting (Motzer et al, 2002). This prognostic model was found to be predictive of survival in an independent data set derived from patients treated at the Cleveland Clinic, providing independent, external validation of the proposed model (Mekhail et al, 2005). Similar prognostic schemes have also been proposed by the Groupe Français d’Immunothérapie (Négrier et al, 2002), the International Kidney Cancer Working Group (Manola et al, 2011), and investigators from the University of California, Los Angeles (Tsui et al, 2000).

Modifications of these prognostic schemes as well as identification of reliable molecular markers are under investigation as

suitable predictors of response to and survival after therapy with newer targeted agents against vascular endothelial growth factor (VEGF) and mammalian target of rapamycin (mTOR) pathway components (Choueiri et al, 2007, 2008b; Motzer et al, 2008a). The most comprehensive effort to define prognostic factors in patients undergoing therapy with VEGF pathway antagonists was undertaken by the International Metastatic Renal Cell Carcinoma Database Consortium. Using data from a group of 645 patients treated with first-line VEGF-targeted agents at several U.S. and Canadian centers, the Database Consortium investigators confirmed the prognostic relevance of several components of the MSKCC model (performance status, hypercalcemia, anemia, and time from diagnosis to treatment); neutrophilia and thrombocytosis were identified as additional, independent predictors of poor outcome (Heng et al, 2009). Patients were divided into three risk categories based on the

number of adverse prognostic factors associated with their disease. This model was validated by the same group in an independent cohort of 849 patients and also shown to be comparable to other prognostic models such as the MSKCC model. In their updated analysis, median OS was 43.2 months in patients with no risk factors, 22.5 months in those with one or two risk factors and 7.8 months in those with three or more risk factors (Heng et al, 2013) (Table 63-2). Validated prognostic models are used in clinical practice to help make appropriate management decisions as well as in the design and interpretation of clinical trials.

SURGICAL MANAGEMENT OF METASTATIC RENAL CELL CARCINOMA

Debulking or Cyto-reductive Nephrectomy in Patients with Metastatic Renal Cell Carcinoma

The role of cytoreductive nephrectomy preceding systemic therapy has been extensively studied in the era of cytokine therapy. The impetus for exploring this approach in metastatic RCC was provided both by the perception that bulky tumors might inhibit key components of the immune system critical for combating cancer and by observations suggesting that removal of large primary tumors may provide clinical benefit. To support this practice, early proponents of cytoreductive nephrectomy had cited (1) the rare but well-described occurrence of spontaneous regression of metastatic lesions after nephrectomy (Bloom, 1973; Middleton, 1980; Snow and Schellhammer, 1982; Marcus et al, 1993); (2) preclinical data suggesting that large primary tumors may inhibit T-cell function (Kudoh et al, 1997; Bukowski et al, 1998; Ling et al, 1998; Uzzo et al, 1999a, 1999b); and (3) the inability of systemic agents, particularly cytokines, to induce meaningful responses in primary renal tumors in most patients (Sella et al, 1993; Rackley et al, 1994; Wagner et al, 1999). However, the risk of perioperative morbidity and mortality and the inability of a significant proportion of patients undergoing nephrectomy to subsequently receive systemic therapy clearly underlined the need for unequivocal evidence of clinical benefit as well as the ability to identify patients likely to benefit from this approach.

Nephrectomy as the sole therapeutic intervention in the context of metastatic disease is unlikely to alter outcome, as

suggested by small retrospective analyses (Dekernion et al, 1978). However, several retrospective studies have demonstrated the feasibility of a combined modality approach in which nephrectomy is followed by cytokine therapy, with some suggesting that this approach may favorably impact response and survival. Investigators from the National Cancer Institute (NCI) reported their experience in 195 patients undergoing nephrectomy followed by high-dose interleukin-2 (IL-2) therapy between the years 1985 and 1996 (Walther et al, 1997b). An overall response rate of 18% (including a complete response rate of 4%) after IL-2 therapy was observed in this study. A notable finding that emerged from this study was that although the majority of patients underwent successful resection of the primary tumor, only 107 of 195 (55%) went on to receive IL-2 therapy. Rapid postoperative disease progression and perioperative surgical and medical morbidity were the most common factors preventing delivery of systemic therapy, suggesting that careful patient selection may play an important role in the successful application of this combined modality approach. The impact of patient and/or disease characteristics on outcome was further highlighted by a retrospective study addressing this issue. In Bennett and associates' (1995) series of 30 patients, which included several patients with unfavorable performance status (Eastern Cooperative Oncology Group [ECOG] 2) and multiple metastatic sites, including patients with brain or liver metastases, only 7 (23%) were able to proceed with IL-2 after nephrectomy. Conversely, in a series that included only patients with favorable clinical/prognostic factors (e.g., good performance status, minimal comorbidity, no liver or brain metastases), the majority of patients were able to proceed to systemic therapy after nephrectomy, with high response rates (35% to 40%) and OS (median 20 to 22 months) after cytokine-based treatment (Fallick et al, 1997; Figlin et al, 1997). More recently, in a population-based analysis of more than 5000 patients with metastatic kidney cancer identified in the Surveillance, Epidemiology, and End Results database, cytoreductive nephrectomy appeared to be associated with a better overall and cancer-specific survival (Zini et al, 2009). Although these retrospective analyses and small single-arm prospective studies confirmed the feasibility of a tandem surgical-cytokine therapeutic approach, their major contribution was in laying the foundation for controlled, prospective studies to determine if outcomes with cytokine therapy could be improved by prior nephrectomy.

The most compelling evidence in support of cytoreductive nephrectomy is provided by two randomized phase III studies

conducted by the Southwest Oncology Group (SWOG) and the European Organisation for Research and Treatment of Cancer (EORTC). The larger of the two studies, SWOG trial 8949, randomized 241 patients with metastatic RCC to receive interferon alfa-2b either as initial therapy or after cytoreductive nephrectomy (Flanigan et al, 2001). Salient eligibility criteria included a histologic diagnosis of kidney cancer (all histologic subtypes were allowed); good performance status (ECOG 0 or 1); presence of a resectable primary renal tumor; no prior chemotherapy, irradiation, or immunotherapy; and adequate organ function. Although there were no significant differences in the response rates to interferon observed in the two study arms, OS was improved in the surgery-plus-interferon arm (median 11.1 vs. 8.1 months for interferon alone, $P = .05$) (Fig. 63-2). These data were recapitulated in a smaller EORTC trial (a total of 85 patients randomized to interferon alone or interferon after nephrectomy) that used a similar design and reported a survival advantage favoring the surgery-plus-interferon arm (median OS 17 vs. 7 months, $P = .03$) (Mickisch et al, 2001). A combined analysis of both trials revealed data that were consistent with those reported in the individual trials (Flanigan et al, 2004). These data support the use of cytoreductive nephrectomy in carefully selected patients with metastatic RCC who are likely candidates for subsequent cytokine therapy (data summarized in Table 63-3). Although some patients with non-clear cell histologic subtypes of RCC were included in the aforementioned trials, the role of nephrectomy before systemic therapy in these patients is unclear.

Although widely employed in standard clinical practice, the impact of cytoreductive nephrectomy on outcome in patients receiving VEGF or mTOR pathway inhibitors remains to be determined and is the subject of ongoing prospective randomized trials. At least one retrospective series suggests that patients with metastatic clear cell RCC benefited from undergoing cytoreductive nephrectomy prior to initiation of systemic therapy (Choueiri et al, 2011). Of 314 patients who had received VEGF pathway antagonists, 201 underwent prior cytoreductive surgery, while the remainder ($n = 113$) proceeded to systemic therapy without surgical debulking of their primary tumor. In a univariate analysis, cytoreductive surgery was associated with a more favorable outcome (median OS 19.8 vs. 9.4 months, hazard ratio [HR] 0.44, 95% confidence interval [CI] 0.32 to 0.59, $P < .01$), a difference that persisted after adjusting for confounding prognostic/risk factors (HR 0.68, 95% CI 0.46 to 0.99, $P = .04$). While these data should be interpreted

Figure 63-2. Actuarial survival among 241 patients with metastatic renal cell carcinoma randomized to either interferon alfa-2b alone or interferon alfa-2b after cytoreductive nephrectomy. (From Flanigan RC, Salmon SE, Blumenstein BA, et al. Nephrectomy followed by interferon alfa-2b compared with interferon alfa-2b alone for metastatic renal-cell cancer. *N Engl J Med* 2001;345:1655–9.)

IFN, interferon alfa-2b; NS, not significant; Nx, cytoreductive nephrectomy.

with caution because of the inherent bias associated with analyses of this nature, these data nonetheless provide some justification for clinicians who continue the practice of cytoreductive nephrectomy in the era of targeted systemic therapy.

Resection of Metastases

Most patients with metastatic RCC will not achieve a cure or long-term disease remission with currently available systemic agents. However, resection of limited metastatic disease has been reported by several groups to be associated with long disease-free intervals and OS in some patients. It should be emphasized that metastasectomy has not been evaluated systematically in a prospective, randomized fashion and that the favorable outcome ascribed to resection in patients with oligometastatic disease may reflect patient selection bias, inherent differences in tumor biology, and natural history or other confounding factors.

Most studies detailing outcome after metastasectomy are retrospective series. In most series, isolated pulmonary metastases were the lesions most commonly amenable to resection with curative intent. The OS of patients undergoing complete resection of limited metastatic disease is quite impressive, with reported median 5-year survival rates of 35% to 50% in many series (Middleton, 1967; Skinner et al, 1971; Tolia and Whitmore, 1975; O'Dea et al, 1978; Pogrebnik et al, 1992; Kierney et al, 1994; Friedel et al, 1999; Murthy et al, 2005; Russo et al, 2007). The larger of these studies have also attempted to identify patients most likely to benefit from this approach. In a series of 278 patients with recurrent RCC treated at MSKCC, 211 were reported to have undergone either complete (141 patients) or incomplete (70 patients) resection of recurrent tumor from a variety of metastatic sites (Kavolius et al, 1998). In this series, complete or "curative" resection was associated with a longer OS (44% 5-year survival vs. 14% in patients undergoing incomplete resection); multivariate analysis also identified the presence of a solitary metastatic lesion, age younger than 60 years, and a disease-free interval of more than 1 year as favorable prognostic indicators. In addition, some studies have suggested that pulmonary metastases, smaller tumor size (<4 cm in one series), and metachronous lesions are predictors of better outcome after metastasectomy (Friedel et al, 1999; Piltz et al, 2002; Murthy et al, 2005). In a retrospective single-institution study of 125 patients who had one or more metastatic lesions surgically removed, Alt and colleagues (2011) confirmed that patients who underwent complete metastasectomy had improved outcomes; furthermore, complete metastasectomy appeared to be both feasible and predictive of improved cancer-specific survival even in patients with multiple metastatic lesions. Although not supported by convincing evidence of survival benefit from prospective studies, resection of isolated metastatic lesions is a reasonable and widely employed practice in selected RCC patients.

Palliative Surgery

Cytoreductive nephrectomy can be performed with palliative intent in patients with intractable pain, hematuria, constitutional symptoms, or a variety of paraneoplastic manifestations

such as hypercalcemia, erythrocytosis, secondary thrombocytosis, or hypertension. Symptoms such as pain and laboratory abnormalities, including hypercalcemia, can often be effectively managed medically, whereas symptoms such as hematuria may be amenable to alternative treatment approaches (e.g., angioembolization). Furthermore, resection of the primary renal tumor does not always result in clinical benefit; for instance, in one series, only a little over half the patients (7 of 12) with hypercalcemia experienced clinically meaningful reductions in serum calcium levels (Walther et al, 1997a). Cytoreductive nephrectomy with palliative intent is therefore performed relatively infrequently but is appropriate in some patients.

Resection of metastases to alleviate pain or to forestall potentially life-threatening or debilitating complications is indicated in a variety of situations. Patients who may benefit from noncurative resection of metastatic lesions include those with solitary brain metastases, metastatic lesions in weight-bearing bones or joints, or vertebral metastatic lesions with impending spinal cord or radicular compromise (Sundaresan et al, 1986; Kollender et al, 2000; Sheehan et al, 2003). Surgical resection is often combined with radiation and/or systemic therapy in many of the aforementioned situations.

KEY POINTS: CYTOREDUCTIVE NEPHRECTOMY IN METASTATIC RENAL CELL CARCINOMA

- Two randomized studies have demonstrated improved survival in carefully selected metastatic RCC patients undergoing cytoreductive nephrectomy followed by cytokine therapy (interferon- α) compared with those receiving cytokine therapy alone.
- Several patient and/or disease characteristics appear to influence outcome; patients with poor performance status, comorbid medical conditions, rapidly progressive disease, and presence of brain metastases are unlikely to benefit from this approach.
- The role of cytoreductive nephrectomy as a prelude to systemic therapy with currently available novel targeted agents is unclear and is being prospectively studied in ongoing clinical trials. A retrospective analysis appears to suggest benefit for cytoreductive nephrectomy in patients treated with first-line sunitinib.

IMMUNOLOGIC APPROACHES IN THE MANAGEMENT OF ADVANCED CLEAR CELL RENAL CELL CARCINOMA

The host immune system has long been believed to play an important role in the causation and control of RCC. A report detailing spontaneous regression of metastatic lesions after radical nephrectomy provides perhaps the earliest evidence implicating the immune system in the regulation of kidney cancer. The phenomenon of

KEY POINTS: METASTASECTOMY

- Resection of isolated metastatic lesions is appropriate in selected patients.
- Several retrospective studies have suggested that patients undergoing complete resection of isolated metastatic foci may experience long disease-free intervals, with median overall survival rates of 35% to 50% in some reports.
- Several factors are associated with an improved outcome after metastasectomy, including complete resection, presence of solitary metastatic lesions, age younger than 60 years, smaller tumor size, presence of pulmonary metastases, and development of metachronous metastatic disease.
- There are no prospective, randomized studies demonstrating a favorable outcome with metastasectomy. It is therefore possible that the favorable outcome after resection of limited metastatic disease may be a reflection of patient selection bias, differences in tumor biology and natural history, or other confounding factors not related to resection.

KEY POINTS: PALLIATIVE SURGERY IN ADVANCED RENAL CELL CARCINOMA

- In some patients with advanced RCC, cytoreductive nephrectomy may help alleviate symptoms related to the primary tumor (e.g., intractable pain, hematuria) or paraneoplastic manifestations.
- However, nonsurgical options are often effective in palliating symptoms associated with RCC; cytoreductive nephrectomy is hence infrequently performed with purely palliative intent.
- Resection of metastatic lesions (often in combination with radiation or systemic therapy) is sometimes performed for relief of symptoms or to prevent life-threatening or disabling sequelae.

spontaneous regression, thought to represent T- or B-cell-mediated antitumor immunity, has sparked great enthusiasm over the years and generated several reports describing this phenomenon (Braren et al, 1974; Silber et al, 1975; Middleton, 1980; Robson, 1982; Snow and Schellhammer, 1982; Kavoussi et al, 1986; Marcus et al, 1993; Edwards et al, 1996). Although rare (it is estimated that the true incidence of spontaneous regression is less than 1%) and often transient, the presumed immunologic mechanisms underlying this event have nonetheless played an important part in the development of immunotherapeutic approaches in kidney cancer. The presence of immune cells, notably cytotoxic T lymphocytes, in resected tumors and the identification of tumor-associated antigens that can serve as human leukocyte antigen (HLA)-restricted targets

on tumor cells for T cell-mediated cytotoxicity have also kindled interest in immune-based strategies in RCC (Finke et al, 1994; Boon et al, 1997; Ada, 1999; Rosenberg, 1999; Takahashi et al, 2008). Early clinical studies explored the efficacy of agents believed to act as nonspecific stimulators of the host immune system, such as cytokines, with or without adoptive cellular therapy. More recently, investigators have evaluated a variety of novel approaches, including allogeneic immunotherapy, vaccines, and modulators of T-cell function. Most immunotherapy strategies have been directed at clear cell RCC, and the utility of these approaches in non-clear cell variants remains to be explored.

Interferons

The interferons are a group of proteins with diverse biologic functions, including immunomodulatory properties. Interferon- α was one of the earliest cytokines to be evaluated for activity in RCC. Initial trials with interferon utilized leukocyte-derived interferon. The subsequent availability of recombinant interferon- α in the early to mid 1980s allowed investigators to evaluate higher doses of this cytokine in a series of phase II trials. Initial trials demonstrated overall response rates of 16% to 26% in patients treated with interferon- α , and several subsequent trials have confirmed the activity of this agent, with response rates generally in the 10% to 15% range (deKernion et al, 1983; Quesada et al, 1983, 1985; Umeda and Nijijima, 1986; Muss et al, 1987; Rosenberg et al, 1987; Figlin et al, 1988; Quesada, 1989; Minasian et al, 1993; Motzer et al, 2002). The limited long-term survival data available suggest that durable complete responses with this agent are relatively rare (<2%). A variety of dosing schedules and routes have been evaluated to determine the optimal interferon regimen; no single mode of administration or dosing schedule has so far demonstrated superiority over others (Kirkwood et al, 1985; Umeda and Nijijima, 1986; Muss et al, 1987; Minasian et al, 1993). Similarly, the addition of chemotherapy or other cytokines to interferon- α has failed to improve the outcomes seen with single-agent therapy (Rosenberg et al, 1989a; Sella et al, 1992; Ravaud et al, 1994, 1998; Ellerhorst et al, 1997; Tourani et al, 1998, 2003; Dorval et al, 1999; Négrier et al, 2000a, 2000b).

Several prospective, randomized trials evaluating the efficacy of interferon- α have demonstrated a modest but statistically significant improvement in outcome after treatment with this agent. A randomized phase III study that assigned 335 patients to receive either interferon alfa or medroxyprogesterone demonstrated a higher response rate (14% vs. 2%) and OS (median 8.5 vs. 6 months, HR 0.72, $P = .017$) favoring the interferon arm of the study (Medical Research Council Renal Cancer Collaborators, 1999). A second study randomized 160 patients with metastatic RCC to receive vinblastine alone or in combination with interferon alfa-2a; a higher response rate (16% vs. 2.5%) and improved OS (median 16 vs. 9 months, $P = .0049$) with the addition of interferon was observed in this study (Table 63-4) (Pyrrhonen et al, 1999). Two additional randomized studies suggested that vinblastine is unlikely to have contributed significantly to the activity of this combination

TABLE 63-4 Summary of Results from Selected Randomized Trials of Interferon- α in Metastatic Renal Cell Carcinoma

by showing that survival was not improved with the addition of vinblastine to interferon alfa (Neidhart et al, 1991; Fossa et al, 1992). Lastly, a meta-analysis of randomized trials of interferon against a variety of agents suggested that interferon-based therapy conferred a survival advantage (Coppin et al, 2005). Despite its relatively modest activity, based on the just-described data and relative ease of administration compared with IL-2, interferon was commonly the agent of choice in the initial treatment of metastatic RCC until the advent of VEGF pathway antagonists.

Interleukin-2

Clinical trials in the early 1980s initially identified IL-2 as an active agent in RCC, with some IL-2-based regimens leading to objective response rates in excess of 30% (Rosenberg et al, 1989b, 1993). In a subsequent report detailing 255 patients treated in a series of phase II trials at the NCI, a more modest overall response rate of 15% (37 of 255 patients) was noted (Fyfe et al, 1996). Several trials conducted by the NCI and the Cytokine Working Group as well as meta-analyses of published data have consistently demonstrated response rates in the range of 15% to 20% (Lotze et al, 1986; Rosenberg et al, 1987, 1989b, 1993; Fisher et al, 1988; Dutcher et al, 1997a). More importantly, 7% to 9% of patients receiving high-dose IL-2 are reported to have achieved complete regression of all metastatic tumor, with the majority of complete responders (>60%) demonstrating no evidence of disease recurrence on long-term follow-up (Fisher et al, 1997, 2000; Rosenberg et al, 1998). There have also been reports of long-term disease-free remission in partial responders whose limited disease burden after IL-2 therapy rendered them amenable to resection of localized metastases. High-dose IL-2 was approved by the U.S. Food and Drug Administration (FDA) for the treatment of metastatic kidney cancer in 1992, based largely on its ability to induce durable complete responses in some patients.

The initial studies with IL-2 were conducted using an intravenous bolus regimen with doses of 600,000 or 720,000 IU/kg administered every 8 hours as tolerated to a maximum of 15 doses. A major limitation of this dosing regimen is the considerable associated toxicity that has limited its widespread use. Vascular leak syndrome and the resulting hypotension, third-space fluid retention, respiratory compromise, and multiorgan damage are some of the more problematic concomitants of IL-2 therapy and led to an unacceptably high treatment-related mortality rate (2% to 5%) in early studies with this agent (Rosenberg et al, 1987; Kammula et al, 1998). Subsequently, careful patient selection, intensive monitoring schemes, and early interventions with intravenous

fluids, vasopressors, and antibiotics have served to significantly reduce mortality associated with IL-2 (Kammula et al, 1998). However, the significant morbidity and expense associated with delivering bolus high-dose IL-2 have led several investigators to explore alternative regimens aimed at reducing toxicity without compromising efficacy. Numerous single-arm phase II studies have evaluated a variety of alternative regimens, including daily subcutaneous administration and continuous intravenous infusion (Escudier et al, 1994a, 1994b, 1995; Négrier et al, 2000b, 2005, 2008; Atkins et al, 2001). Many of these studies have reported overall response rates of 10% to 30%, suggesting comparable efficacy to high-dose bolus administration based on data from historical controls. However, two randomized studies have demonstrated that, although well tolerated, lower-dose regimens are associated with lower overall response rates, as well as with fewer durable, complete responses (Table 63-5) (Yang et al, 2003b; McDermott et al, 2005). Based on these data, we only recommend high-dose IL-2 regimens in patients being considered for cytokine therapy.

Attempts to enhance the efficacy of IL-2 therapy have led investigators to explore combination therapy with other cytokines, cytotoxic chemotherapy, and adoptive cellular immunotherapy. Early experience with combination cytokine therapy was promising, with one study reporting a 31% overall response rate in patients treated with high-dose bolus IL-2 and interferon (Rosenberg et al, 1989a). However, subsequent studies have indicated that this combination is more toxic and no more effective than IL-2 alone (Ravaud et al, 1994; Bukowski et al, 1997; Dutcher et al, 1997b; Tourani et al, 1998, 2003). A multicenter, randomized phase III study compared the efficacy of intermediate-dose IL-2 administered by continuous intravenous infusion with interferon alfa-2a or the combination in 425 patients with metastatic clear cell RCC (Négrier et al, 1998). Although the combination of IL-2 and interferon resulted in a higher response rate (18.6%) and 1-year event-free survival (EFS; 20%) compared with IL-2 (overall response rate 6.5%, 1-year EFS 15%) or interferon (overall response rate 7.5%, 1-year EFS 12%) alone, there was no significant difference in survival between the groups (Fig. 63-3). Combination therapy also resulted in higher toxicity than either agent given alone. Regimens combining IL-2 and cytotoxic chemotherapy (particularly 5-fluorouracil [5-FU]) have been the subject of numerous studies. Unfortunately, reports of high response rates in initial studies (49% in a study using IL-2, interferon, and 5-FU) could not be reproduced in later studies (Atzpodi et al, 1993; Ellerhorst et al, 1997; Dutcher et al, 2000; Négrier et al, 2000a). Similarly, despite the promise of preclinical and early clinical studies, the addition of ex vivo expanded tumor-infiltrating lymphocytes or lymphokine-activated killer cells to

high-dose IL-2 has not reliably demonstrated improved clinical benefit and these approaches have been largely abandoned (Rosenberg et al, 1993; Law et al, 1995; Figlin et al, 1999).

Given the considerable toxicity associated with high dose IL-2 and the relatively small proportion of patients who derive benefit from this therapy, identification of predictors of response and long-term outcome has received considerable attention. The predictive value of a variety of histologic, clinical, laboratory, and molecular parameters has been studied. Patients with clear cell RCC appear most likely to benefit from IL-2 therapy, although the exceedingly small number of patients with non-clear cell histologies typically enrolled in studies of IL-2 makes it difficult to draw definitive conclusions about efficacy in this subgroup of patients. Patient performance status, number of metastatic sites, site of metastases, prior nephrectomy, and time from nephrectomy to systemic therapy are some of the factors that may impact outcome. In one study, patients with more than one site of metastasis, those with metastatic disease within 1 year of diagnosis, and those with liver metastases had the worst outcome, with a median survival of 6 months (Négrier et al, 2002). Overexpression of carbonic anhydrase IX (CA-IX or G250) has been observed in a retrospective analysis to be associated with a higher probability of response to IL-2 (Atkins et al, 2005); however, a prospective trial of 120 advanced kidney cancer patients designed to evaluate the impact of prespecified "good risk" clinical features or biomarkers (i.e., CA-IX) on outcome revealed that CA-IX expression was not predictive of response (McDermott et al, 2010). The role of cytokine therapy in the current management of kidney cancer has changed with the availability of novel inhibitors of VEGF and mTOR pathways with activity in clear cell RCC. Single-agent interferon, the previous standard in many institutions, is no longer used in the first-line treatment of clear cell RCC. However, given the inability of newer targeted agents to induce durable responses, high-dose intravenous IL-2 remains a reasonable option in the initial therapy of carefully selected patients with metastatic clear cell RCC.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation allows the replacement of host or recipient immune and hematopoietic systems with those of a healthy, HLA-compatible donor. The therapeutic potential of hematopoietic stem cell transplantation lies largely in the ability of the transplanted donor graft to generate an allogeneic antitumor immune response known as the graft-versus-tumor effect. This approach has been used successfully with curative

intent in a variety of hematologic malignancies (Thomas et al, 1977; Weiden et al, 1979, 1981). The ability of a variety of immune-based approaches to induce remissions in patients with RCC and evidence suggesting that the host immune system in these patients may be compromised and/or tolerant to tumor cells have led several investigators to evaluate allogeneic hematopoietic stem cell transplantation in kidney cancer.

The approach was initially studied by investigators at the National Heart, Lung and Blood Institute exploring the efficacy of reduced-intensity hematopoietic stem cell transplantation in patients with treatment-refractory metastatic RCC. Eligible patients underwent reduced-intensity conditioning with cyclophosphamide (120 mg/kg) and fludarabine (125 mg/m²) followed by infusion of a granulocyte colony-stimulating factor-mobilized peripheral blood stem cell graft from a 5 of 6 or 6 of 6 HLA-matched sibling donor. The initial experience with hematopoietic stem cell transplantation in metastatic RCC was published by Childs and colleagues (2000). Ten of the first 19 patients treated with this transplant approach had tumor shrinkage, including 3 who had a complete response and 7 who had a partial response. As more recently reported, 74 patients have undergone hematopoietic stem cell transplantation for RCC at the National Institutes of Health. Of these, 73 patients have demonstrated durable engraftment, achieving 100% donor T-cell chimerism by day 100 post-transplant. Twenty-nine of 74 patients (39%) have had a disease response, including 7 complete (9%) and 22 partial (30%) responders (Takahashi et al, 2008). Preliminary data suggest that disease response after hematopoietic stem cell transplantation is a clinically meaningful phenomenon because regression of metastatic RCC appears to be associated with a trend toward improved survival. Survival in nonresponders has been less than 6 months, in contrast to those achieving a partial response, who survived a median 2.5 years post-transplant. Several durable responses have been noted, and the first patient who underwent a transplant remains in complete remission more than 10 years after the procedure. Hematopoietic stem cell transplantation is associated with a variety of adverse events typically associated with conditioning chemotherapy (e.g., pancytopenia), a variety of opportunistic infections, and graft-versus-host disease (GVHD). Eight patients in the just-mentioned series died of transplant-related causes (transplant-related mortality of 11%), most due to GVHD and its attendant infectious complications.

Several other trials have since confirmed the efficacy of this approach in RCC (Table 63-6) (Rini et al, 2001, 2002; Bregni et al, 2002; Artz et al, 2005; Barkholt et al, 2006). However, a Cancer and Leukemia Group B (CALGB) intergroup trial evaluating the feasibility of performing hematopoietic stem cell transplantation for metastatic RCC in a multi-institutional setting in the United States reported no responses in 22 patients undergoing hematopoietic stem cell transplantation from an HLA-matched sibling donor after cyclophosphamide/fludarabine-based conditioning (Rini et al, 2006). Median OS was only 5.5 months, with most patients dying of disease progression (median time to progression of 3 months). Inclusion of a number of patients with multiple adverse prognostic factors, sparing use of donor lymphocyte infusions (only 2 of 22 patients received donor lymphocyte infusions despite disease progression in the majority), and inclusion of patients with non-clear cell histology are some of the factors that may account for the poor outcome observed in this trial. This trial clearly highlights the importance of appropriate patient selection and the need for identifying prognostic factors likely to predict for a favorable outcome. In a European multicenter study of 106 patients undergoing transplantation, chronic GVHD, good performance status (Karnofsky score = 80), administration of donor lymphocyte infusions, and fewer than three sites of metastatic disease were identified as factors favorably impacting survival (Barkholt et al, 2006). Given the high morbidity and mortality with this approach, careful patient selection is of great importance. Hematopoietic stem cell transplantation remains an experimental approach in the management of RCC; strategies for minimizing the toxicity associated with this procedure and maximizing

antitumor effects are being explored and are required to render this approach more widely applicable.

Immune “Checkpoint” Inhibitors

The host immune response to tumors is a highly complex process that is regulated at multiple levels. The interplay between multiple stimulatory and inhibitory processes determines the nature and extent of the antitumor response generated by the host immune system. Over the last few years, it has become increasingly evident that several inhibitory receptors on effector immune cells, such as CD8⁺ T lymphocytes, play a key role in tightly regulating the immune response to tumors. Furthermore, antitumor responses can be downregulated by activation of T-cell receptors such as cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) and those mediating programmed death-1 (PD-1).

Pharmacologic targeting of immune checkpoints such as CTLA-4 and the PD-1 axis is being explored currently in many solid tumors, including RCC. A single-arm phase II study of ipilimumab, a monoclonal antibody targeting CTLA-4, demonstrated activity in patients with clear cell RCC, including in some who had previously progressed following IL-2 therapy (Yang et al, 2007). The most notable side effects associated with this agent included autoimmune events such as enteritis and hypophysitis. While autoimmune adverse events were highly predictive of response, they were sufficiently severe enough (grade 3-4 in up to a third of the patients) to dampen enthusiasm for further development of this agent in RCC.

More recently, both PD-1 and its ligands (PD-L1, PD-L2) have attracted attention as potential antitumor targets. While PD-1 is expressed on CD⁺ T cells, PD-L1 and PD-L2 are expressed on the surface of tumor cells; patients whose tumors contain PD-1-positive tumor-infiltrating lymphocytes are more likely to have larger tumors, higher grade tumors, advanced-stage RCC, and sarcomatoid differentiation than patients without PD-1-positive tumor-infiltrating lymphocytes (Thompson et al, 2007). Engagement of PD-1 on T cells by its ligand leads to downregulation of antigen-driven immune responses (Fife et al, 2009; Sznol et al, 2013).

Several antibodies targeting the PD-L1 checkpoint are currently in clinical evaluation (Brahmer et al, 2012; Topalian et al, 2012; Drake et al, 2013). In a large phase I study with multiple expansion cohorts, patients with advanced melanoma, non-small cell lung cancer, castration-resistant prostate cancer, colorectal cancer, or renal cancer were treated with nivolumab (anti-PD-1 antibody) (Topalian et al, 2012). A total of 33 RCC patients were enrolled, and 9 patients (27%) had an objective response. Despite the fairly short follow-up, several durable responses were evident, with five patients demonstrating a response lasting 1 year or more. Furthermore, stable disease lasting 24 weeks or more was seen in an

additional nine patients (27%). Interestingly, pretreatment tumor specimens from 42 patients (5 with RCC) were analyzed for PD-L1 expression on the surface of tumor cells. None of the 17 patients with PD-L1-negative tumors experienced a response while 9 of 25 (36%) with PD-L1 expression had an objective response, suggesting that PD-L1 expression should be further evaluated as a predictive biomarker. As anticipated, several patients experienced adverse events of possible autoimmune etiology, including diarrhea, hypophysitis, and vitiligo.

A second phase I, dose-escalating study evaluating inhibition of the PD-1 checkpoint was conducted with BMS-936559, a PD-L1-specific monoclonal antibody, in patients with advanced solid tumors (Brahmer et al, 2012). Of 75 patients, 17 had RCC; 2 of the 17 RCC patients (12%) had an objective response lasting 4 and 17 months, respectively. Seven additional patients (41%) had stable disease lasting at least 24 weeks.

While promising, these data were obtained from small patient cohorts with a short follow-up duration and must be interpreted with caution. Data from more definitive, ongoing trials of PD-1 and PD-L1 inhibitors are awaited and will determine if the enthusiasm engendered by the phase I data is justified.

MOLECULAR BASIS FOR TARGETED APPROACHES IN CLEAR CELL RENAL CELL CARCINOMA

The development of antagonists of the VEGF pathway in the treatment of clear cell RCC is an often-cited paradigm in the evolution of rational targeted therapeutic strategies and represents a logical progression from identification of an oncogenic cellular pathway to rational drug design and structured clinical evaluation. The earliest clues to the central role played by VEGF in renal oncogenesis came from studies attempting to identify the genetic basis of the von Hippel-Lindau familial kidney cancer syndrome. In the early 1990s, investigators at the NCI studying families with von Hippel-Lindau disease used genetic linkage analysis to identify germline mutations or deletions in the von Hippel-Lindau gene (*VHL*) as the basis for this disease (Latif et al, 1993). Individuals carrying germline *VHL* mutations are at increased risk for developing tumors in multiple organs, including bilateral, multifocal clear cell kidney cancer. The *VHL* gene is a classic tumor suppressor gene, with inactivation of the normal *VHL* allele in affected tissues by a somatic “second hit” required for tumor formation.

The *VHL* gene resides on the short arm of chromosome 3 and encodes the von Hippel-Lindau protein (VHL), which can be synthesized as two alternatively spliced variants (Latif et al, 1993; Gnarr et al, 1996; Iliopoulos et al, 1998; Linehan, 2003). One

of the better-understood functions of the VHL protein is its association with elongins B and C and Cullin 2 (CUL2) to form a protein complex that serves to tag certain cellular proteins for delivery to and degradation by the ubiquitin system (Duan et al, 1995; Pause et al, 1997; Stebbins et al, 1999; Linehan, 2003; Kaelin, 2004). Proteins targeted for ubiquitin-mediated degradation include the α subunits of a group of transcriptionally active proteins known as hypoxia-inducible factors (HIFs) (Iliopoulos et al, 1996; Pause et al, 1997; Maxwell et al, 1999; Cockman et al, 2000; Ohh et al, 2000; Ivan et al, 2001; Jaakkola et al, 2001). In cells with intact VHL function, HIF levels are primarily controlled by ambient oxygen tension. In normoxic conditions, hydroxylation of key proline residues on HIF promotes its association with the VHL/elongin/CUL complex and subsequent degradation; conversely, hypoxia impedes prolyl hydroxylation of HIF and its subsequent degradation, leading to intracellular accumulation of HIF α subunits. Mutations in *VHL* interfere with its binding to either HIF or elongin/CUL2 and promote HIF accumulation even under normoxia. HIF accumulation, in turn, leads to the upregulation of a variety of proangiogenic and growth factors, including VEGF, platelet-derived growth factor (PDGF), transforming growth factor- α , glucose transporter 1, and erythropoietin, which are believed to play critical roles in the development and progression of clear cell RCC (Fig. 63-4) (Duan et al, 1995; Iliopoulos et al, 1996; Kaelin, 2004; Linehan et al, 2007, 2010a). Although originally identified as a germline defect in von Hippel-Lindau families, evidence of somatic *VHL* inactivation by mutation or promoter hypermethylation has been observed in a high proportion of sporadic clear cell tumors (91% in a recent series) (Herman et al, 1994; Gnarr et al, 1996; Zhuang et al, 1996a, 1996b; Nickerson et al, 2008). The recognition of VHL loss as a central event in renal oncogenesis has paved the way for the development of novel agents targeting components of this pathway in the management of metastatic clear cell RCC.

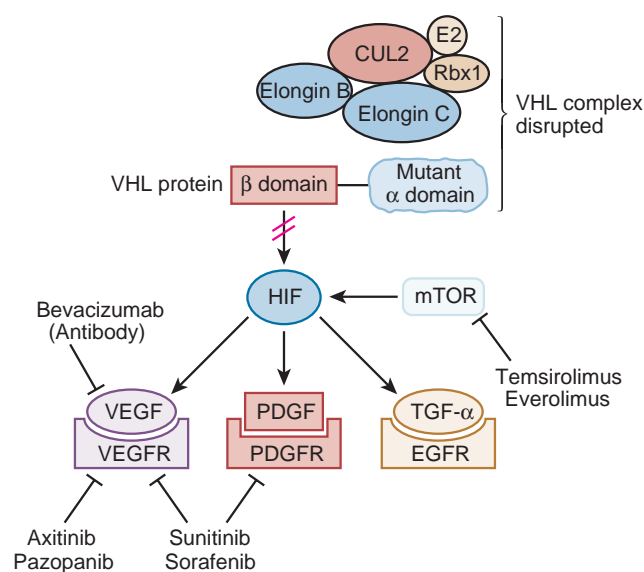

Figure 63-4. Targeting the von Hippel-Lindau (VHL) pathway in clear cell renal cell carcinoma. Loss of VHL activity leads to accumulation of hypoxia-inducible factor (HIF) and several proangiogenic and growth factors that can serve as targets for anticancer drugs. HIF can also be upregulated by mammalian target of rapamycin (mTOR), which promotes HIF translation. EGFR, epidermal growth factor receptor; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; TGF- α , transforming growth factor- α ; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor. TARGETED MOLECULAR AGENTS IN CLEAR CELL RENAL CELL CARCINOMA

Antagonists of the Vascular Endothelial Growth Factor Pathway

Bevacizumab

Bevacizumab, a humanized monoclonal antibody against VEGF-A, was the first VEGF pathway antagonist used in clinical trials to test the hypothesis that modulation of aberrantly expressed components of the VHL pathway would be associated with clinical activity in clear cell RCC. In a three-arm phase II study, patients with metastatic clear cell RCC whose disease had progressed after prior cytokine therapy were randomized to receive either one of two dose levels of bevacizumab (10 mg/kg or 3 mg/kg administered every 2 weeks intravenously) or placebo (Table 63-7) (Yang et al, 2003a). An interim efficacy analysis performed after 116 patients (of a planned 240 patients) were enrolled in the study demonstrated a significantly longer progression-free survival (PFS) in patients assigned to 10 mg/kg bevacizumab compared with those receiving placebo (4.8 vs. 2.5 months, $P < .001$) (Fig. 63-5). There was no corresponding improvement in OS, although the crossover design used in this trial (patients progressing on placebo were allowed to cross over to bevacizumab) may have influenced this outcome. The overall response rate in patients receiving bevacizumab was modest (objective response rate of 10%, all in patients assigned to the 10-mg/kg dose). The agent was well tolerated, with bleeding, hypertension, fatigue, and proteinuria being some of the more common adverse events reported. Single-agent bevacizumab has not been compared with either cytokines (often used in first-line treatment before the advent of VEGF pathway antagonists) or other VEGF pathway antagonists such as sunitinib in prospective trials.

Several strategies for improving the efficacy of bevacizumab have been explored, including combination with cytokines (interferon- α) and other targeted agents (e.g., erlotinib, a small molecule inhibitor of epidermal growth factor receptor tyrosine kinase activity). A single-arm phase II study of bevacizumab plus erlotinib showed promising activity with an overall response rate of 25% (higher than would be expected with bevacizumab alone based on historical data) and median PFS of 11 months (Hainsworth et al, 2005). However, a subsequent randomized phase II study failed to demonstrate the superiority of this combination (median PFS 9.9 months) over bevacizumab alone (median PFS 8.5 months, $P = .58$) in patients with advanced clear cell RCC (Bukowski et al, 2007). Two large randomized phase III studies have compared the combination of bevacizumab and interferon α to interferon α alone (see Table 63-7). In the CALGB 90206 study of 752 patients with previously untreated metastatic clear cell RCC randomized to one of two treatment arms, a higher response rate (25.5% vs. 13.1%, $P < .0001$) and PFS (8.5 vs. 5.2 months, $P < .0001$) were observed in patients assigned to bevacizumab plus interferon α compared with those receiving interferon α alone (Rini et al, 2008a). A multicenter European trial (AVOREN) with a similar design also reported similar results with PFS (10.2 vs. 5.4 months, $P = .0001$) and an objective response rate (31% vs. 13%) favoring the combination arm (Fig. 63-6) (Escudier et al, 2007b). Updated survival data from both trials were reported, demonstrating no improvement in overall survival associated with the addition of bevacizumab to interferon (Escudier et al, 2010; Rini et al, 2010). While neither study permitted crossover of patients assigned to interferon α at progression, a significant number of patients (>60%) subsequently received anticancer therapy off protocol, potentially confounding overall survival analysis. Both trials reported a higher incidence of some grade 3 adverse events such as hypertension, fatigue, anorexia, and asthenia in patients receiving combination therapy. The CALGB and AVOREN trials were large, well-designed, and well-conducted multicenter studies that suggest that the addition of bevacizumab to interferon may be associated

TABLE 63-7 Summary of Selected Studies of Bevacizumab-Based Regimens in Metastatic Renal Cell Carcinoma

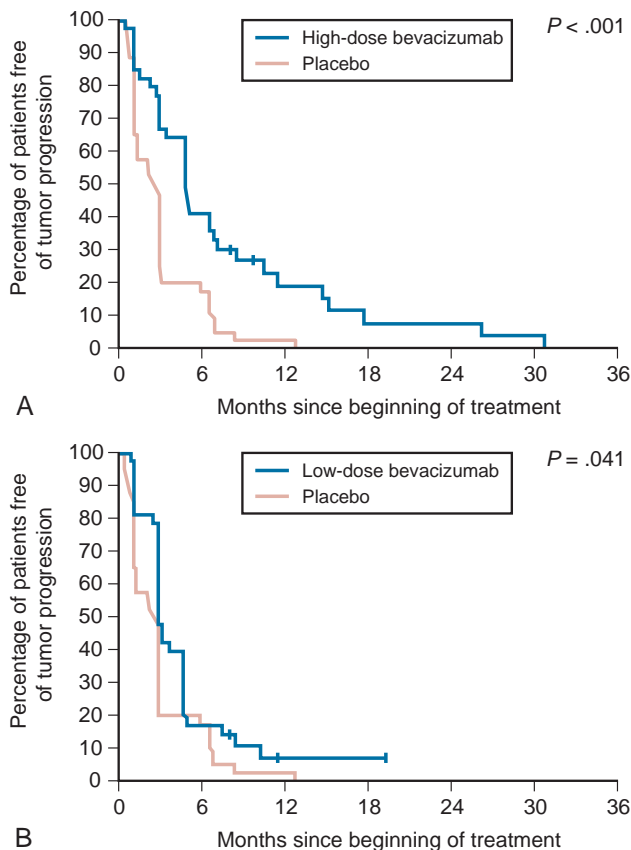

Figure 63-5. Kaplan-Meier analysis of 39 patients assigned to high-dose bevacizumab (10 mg/kg; A) and 37 patients assigned to low-dose bevacizumab (3 mg/kg; B) compared with 40 patients assigned to receive placebo. (From Yang JC, Haworth L, Sherry RM, et al. A randomized trial of bevacizumab, an anti-vascular endothelial growth factor antibody, for metastatic renal cancer. *N Engl J Med* 2003;349:427–34.)

with clinical benefit (i.e., improvement in PFS). However, these trials did not include an arm with bevacizumab alone (owing to insufficient evidence of single-agent activity at the time these trials were designed to justify a bevacizumab-only arm), making it difficult to determine if inclusion of interferon in this regimen, with its attendant toxicities, adds meaningful clinical benefit. Interestingly,

the median PFS observed in the combination arm of the CALGB trial (8.5 months) is similar to that observed with bevacizumab alone in a phase II trial of previously untreated patients with clear cell RCC (Bukowski et al, 2007). Lastly, bevacizumab (either alone or in combination with interferon) has not been compared prospectively with VEGF receptor (VEGFR) antagonists such as sunitinib or pazopanib, arguably the current standard of care for most newly diagnosed patients with metastatic clear cell RCC. Bevacizumab is not widely used as a single agent in the initial therapy for metastatic clear cell RCC but may have a role in patients who have failed standard therapy with first-line VEGFR antagonists, either alone or in combination with other agents, particularly interferon. Ongoing and future trials may help determine the best use of this agent in the overall management of patients with clear cell RCC.

Sorafenib

Sorafenib is an oral receptor kinase inhibitor with activity against VEGFR-2, PDGF receptor- β (PDGFR- β), and raf-1. A phase II trial using a randomized discontinuation design provided initial evidence that sorafenib is active in RCC (Table 63-8) (Ratain et al, 2006). Two hundred and two patients were enrolled in this trial, and all of them received 400 mg of sorafenib twice daily for the first 12 weeks. Sixty-five patients who demonstrated stable disease at the end of this period (defined in this trial as within $\pm 25\%$ of baseline) were then randomized either to continued treatment with sorafenib or to placebo. Patients randomized to sorafenib had a superior PFS (24 weeks) versus those receiving placebo (6 weeks, $P = .0087$). A global, multicenter, placebo-controlled randomized phase III trial with 903 patients (the TARGET study) was subsequently undertaken to evaluate the efficacy of sorafenib in patients with metastatic RCC who had previously received cytokine therapy (Fig. 63-7) (Escudier et al, 2007a). This trial echoed the results seen in the phase II trial, with patients randomized to receive sorafenib experiencing a longer PFS (median 5.5 months) versus those receiving placebo (2.8 months, $P < .01$) at a planned interim analysis. After this interim analysis, patients progressing on placebo were allowed to cross over to receive sorafenib. Mature survival data from this trial were subsequently presented and demonstrated no significant difference in OS between the two groups (17.8 months for sorafenib vs. 15.3 months with placebo, $P = .146$) in an intent-to-treat analysis (see Fig. 63-7) (Escudier et al, 2009a). However, if patients who crossed over from placebo to sorafenib were censored, the survival data demonstrated a statistically significant advantage favoring sorafenib (median OS 17.8 vs. 14.3 months, $P = .029$). Results from this exploratory “pre-cross-over” survival analysis suggest that the

survival end point may have been influenced by the crossover design. Overall response rate to sorafenib in this trial was relatively low, with 10% of patients experiencing a partial response; however, more than 70% of patients receiving sorafenib had some degree of tumor regression.

The side effect profile of sorafenib is comparable to that of other agents in this class and includes hypertension, fatigue, rash, hand-foot syndrome, and diarrhea. The efficacy of sorafenib in the first-line setting was investigated in a randomized phase II study that assigned 189 previously untreated patients with

metastatic clear cell RCC to receive either sorafenib or interferon alfa-2a (Escudier et al, 2009b). Although patients receiving sorafenib had a higher likelihood of achieving tumor regression (68% vs. 39%), PFS in the two groups was nearly identical (median 5.7 months for sorafenib vs. 5.6 months for interferon, $P = \text{NS}$) (see Table 63-8). Although sorafenib is FDA-approved for the treatment of advanced kidney cancer, its precise role in the management of these patients remains to be determined

in view of the plethora of VEGFR antagonists currently available or under investigation. Dose-intensive regimens of sorafenib (up to 800 mg twice daily) have been explored in an attempt to enhance the efficacy of this agent, but to date there is no convincing evidence that higher doses offer additional clinical benefit. Currently, sorafenib is infrequently used in the first-line setting. Anecdotal evidence and small case series suggest that patients whose disease has progressed on other VEGFR inhibitors may respond favorably to sorafenib, and the agent is commonly used in patients whose disease has progressed on sunitinib or similar agents.

Sunitinib

Sunitinib is an oral VEGFR kinase inhibitor widely used in the initial treatment of metastatic clear cell RCC. It is a potent inhibitor of VEGFR-2, PDGFR- β , c-Kit, and fms-like tyrosine kinase 3 (Flt3). As with sorafenib, simultaneous targeting of VEGF and PDGF pathways by this agent is likely to act synergistically in inhibiting tumor angiogenesis, by directly disrupting VEGF-mediated vascular endothelial development and proliferation and by interfering with vascular pericyte function, which is dependent on the integrity of PDGF signaling. Initial evaluation of sunitinib was undertaken with two single-arm open-label phase II trials in patients with metastatic RCC, most of whom had previously received cytokine therapy (Motzer et al, 2006a, 2006b). Sunitinib was administered orally at a dose of 50 mg/day during the first 4 weeks of a 6-week cycle in both trials (Table 63-9). Remarkably high overall response rates (30% to 40%) with a median PFS of more than 8.5 months were observed in these trials, leading to the approval of this agent for treatment of advanced RCC by the FDA. A landmark phase III randomized trial comparing sunitinib with interferon- α as first-line therapy in patients with metastatic clear cell RCC further demonstrated the activity of sunitinib in this patient population (Motzer et al, 2007). In this study, 750 patients were randomized to receive either sunitinib or interferon alfa. An interim analysis based on independent, third-party radiologic assessment demonstrated a significantly superior PFS (median 11 vs. 5 months, $P = .001$) and overall response rate (31% vs. 6%, $P = .001$) favoring the sunitinib arm (Fig. 63-8). Gastrointestinal events, particularly diarrhea, dermatologic manifestations such as rash and hand-foot syndrome, constitutional symptoms such as fatigue and asthenia, and hypertension were the most common adverse events associated with sunitinib; bone marrow suppression and hypothyroidism were other notable side effects. Sunitinib also performed better than interferon in a quality-of-life assessment conducted as part of the study. Mature survival data from this study were subsequently reported and demonstrated a clear trend toward superior OS in the sunitinib study arm based on an intent-to-treat analysis (median OS 26.4 vs. 21.8 months, $P = .051$) (Motzer et al, 2009). Based on these data, sunitinib is widely used in the initial management of metastatic clear cell RCC patients in the United States.

Pazopanib

Agents such as sunitinib and sorafenib have activity against a wide array of target molecules, some of which may not be relevant in clear cell RCC. Although these agents are relatively well tolerated when compared with conventional cytotoxic chemotherapy, dose reductions and termination of treatment because of toxicity are not infrequently warranted in patients receiving these drugs. A variety of newer agents with selective activity against the VEGFR family have recently gained attention as a possible means of diminishing the side effects associated with therapy without compromising efficacy (Table 63-10). One agent in this class, pazopanib, is a potent inhibitor of the VEGF receptors but retains activity against PDGFR.

Pazopanib was evaluated in a randomized, double-blind, placebo-controlled phase III trial in patients with metastatic clear cell RCC who had received no or one prior cytokine-based therapy (Sternberg et al, 2010). In the 435 patients randomized (2:1) to receive either pazopanib or placebo, PFS (median 9.2 vs. 4.2 months, $P = .0000001$) and response rates (30% vs. 3%) clearly favored the pazopanib study arm. Pazopanib was associated with superior outcomes in both the treatment-naïve subpopulation ($N = 233$, median PFS 11.1 vs. 2.8 months, HR 0.40, 95% CI 0.27 to 0.60, $P < .0001$) and the cytokine-pretreated subpopulation ($N = 202$, median PFS 7.4 vs. 4.2 months, HR 0.54, 95% CI 0.35 to 0.84, $P < .001$). Furthermore, reported toxicities were mild, with very few grade 3 and 4 adverse events encountered. However,

mature survival data from this trial demonstrated that OS was not significantly better in the pazopanib arm compared to placebo (median OS 22.9 vs. 20.5 months, HR 0.91, 95% CI 0.71 to 1.16, one-sided $P = .224$) ([Sternberg et al, 2013](#)).

The efficacy and/or tolerability of pazopanib and sunitinib were subsequently compared in at least two studies. In a recently published multicenter phase III randomized trial (COMPARZ) of 1110 patients with previously untreated metastatic clear cell kidney cancer comparing the efficacy and safety of the two agents, patients were randomized to receive either pazopanib 800 mg once daily ($N = 557$) or a standard sunitinib regimen (50 mg once daily for 4 weeks followed by 2 weeks with no treatment, $N = 553$) ([Motzer et al, 2013c](#)). The primary end point was PFS and the study was powered to evaluate noninferiority of pazopanib versus sunitinib. Secondary end points included OS, quality of life, and safety. Median PFS in patients treated with pazopanib was 8.4 months compared to 9.5 months for sunitinib. Based on predefined criteria, PFS with pazopanib was determined to be noninferior to sunitinib (HR 1.05, 95% CI 0.90 to 1.22). OS was comparable in the two groups, with a median OS of 28.4 months in the pazopanib group versus 29.3 months in the sunitinib group (HR 0.91, 95% CI 0.76 to 1.08). However, differences were noted between the two groups in the adverse event profile and patient tolerability. Patients treated with sunitinib had a higher incidence of fatigue (63% vs. 55%), thrombocytopenia (78% vs. 41%), and hand-foot syndrome (50% vs. 29%), while increased levels of alanine aminotransferase were more common in the pazopanib group (60% vs. 43%). Quality-of-life assessments related to fatigue or soreness in the mouth, throat, and hands or feet during the first 6 months of treatment favored pazopanib. Results from a second, smaller study evaluating patient preference between pazopanib and sunitinib (PISCES) were reported in abstract form ([Escudier et al, 2012](#)). One hundred and sixty-eight previously untreated patients with metastatic clear cell RCC were randomized to receive pazopanib for 10 weeks followed by a 2-week washout and then sunitinib for 10 weeks (on a 4-week-on/2-week-off schedule) or vice versa. After completing 22 weeks of therapy, the patients were asked to complete a questionnaire assessing which agent they preferred. Pazopanib was preferred by 70% of the patients, while sunitinib was preferred by 22% of the patients (8% had no specific preference between the agents). **Based on these data, pazopanib is a reasonable first-line option for patients with advanced clear cell RCC. Although pazopanib appears to be better tolerated than sunitinib by the majority of patients, it appears to be associated with an increased incidence of hepatotoxicity and must be used with caution in patients at risk for this complication. It should be further noted that at least**

some patients found sunitinib more tolerable than pazopanib. Decisions regarding which of these agents should be initiated in a given patient should be made after careful, individualized evaluation of each patient.

Axitinib

Axitinib is a highly selective oral small molecule tyrosine kinase inhibitor of VEGF receptors VEGFR-1, VEGFR-2, and VEGFR-3. In a phase II trial of axitinib in 52 patients with advanced kidney cancer, an overall response of 44%, including two complete responses (4%), and a median time to progression of 15.7 months were reported ([Rixe et al, 2007](#)). Most patients treated in this study displayed some degree of tumor shrinkage, and many had been pretreated with either IL-2 or interferon. Diarrhea, fatigue, and hypertension were the most commonly encountered grade 3 and 4 adverse events and were amenable to medical management in most patients. Axitinib was the subject of a recently concluded phase III trial (AXIS) that compared its efficacy to sorafenib (a first-generation VEGFR and RAF inhibitor) in the second-line setting ([Rini et al, 2011; Motzer et al, 2013b](#)). In this study, 723 patients with clear cell RCC who progressed on one first-line therapy containing sunitinib, bevacizumab, temsirolimus, or cytokines were randomized to receive axitinib (starting dose of 5 mg orally twice daily, $N = 361$) or sorafenib (400 mg orally twice daily, $N = 362$). Patients in the axitinib arm were allowed to receive higher doses (up to 10 mg orally twice daily) if lower dose levels were well tolerated; there was no dose escalation in the sorafenib arm. Median PFS, as measured by Response Evaluation Criteria in Solid Tumors (RECIST), was 6.7 months in the axitinib arm compared to 4.7 months in the sorafenib arm (HR 0.665, 95% CI 0.544 to 0.812, $P < .0001$). The benefit from axitinib was most pronounced in patients who had previously received cytokines (median PFS 12.1 months for axitinib vs. 6.5 months for sorafenib, HR 0.464, 95% CI 0.318 to 0.676, $P < .0001$). Patients previously treated with a VEGF pathway antagonist also appeared to benefit, although the improvement in PFS was modest. For instance, in patients who had received sunitinib in the first-line setting, median PFS was 4.8 months with axitinib and 3.4 months with sorafenib (HR 0.741, 95% CI 0.573 to 0.958, $P = .0107$). Overall survival in the two arms was comparable, with a median OS of 20.1 months (95% CI 16.7 to 23.4) with axitinib and 19.2 months (95% CI 17.5 to 22.3) with sorafenib (HR 0.969, 95% CI 0.800 to 1.174, one-sided $P = .3744$). **Based on the improved PFS compared to sorafenib in the AXIS trial, axitinib was approved by the FDA for use in the second-line setting in patients with advanced RCC. In**

both the AXIS trial and prior studies of axitinib, significant inter-patient variability in pharmacokinetics and drug exposure was observed, with higher exposures associated with superior activity. A phase II study in previously untreated clear cell RCC patients employed a dose titration scheme based on clinical tolerability in an attempt to enhance activity by optimizing drug dosing and exposure (Rini et al, 2013). A total of 213 patients were enrolled in this trial, with 112 patients tolerating the drug well enough at the starting dose (5 mg PO bid) to be eligible for dose escalation. These patients were randomized to either an axitinib dose titration arm (7 mg PO bid, increased to 10 mg PO bid if well tolerated; n = 56) or a placebo titration arm (patients remained on 5 mg PO bid; n = 56). Response rates were significantly higher in the dose titration arm (overall response rate = 54%) compared to the placebo arm (overall response rate = 34%, one sided $P = .019$); however, the higher response rates did not translate to an improved PFS. Although these data suggest the possibility that dose titration in individual patients based on tolerability may be advantageous, this approach requires further study.

Other Agents Targeting the VEGF Pathway

Tivozanib, yet another highly selective inhibitor of VEGFR-1, -2, and -3, was evaluated in a phase II randomized discontinuation trial with demonstration of activity in RCC as well as an appealing adverse event profile (Bhargava et al, 2009). Subsequently, Motzer and colleagues (2013d) compared the activity of tivozanib versus sorafenib in advanced RCC in a phase III randomized, open-label, multicenter trial. Patients with advanced RCC with a clear cell component and no prior exposure to VEGF- or mTOR-targeted agents were randomized to receive either tivozanib (N = 260) or sorafenib (N = 257). Tivozanib was associated with a statistically meaningful improvement in PFS (median 11.9 months for tivozanib vs. 9.1 months for sorafenib, HR 0.797, 95% CI 0.639 to 0.993, $P = .042$). The overall response rate was 33% for tivozanib versus 23% for sorafenib ($P = .037$). However, there was a trend toward improved survival in the sorafenib arm (median 29.3 vs. 28.8 months, HR 1.245, 95% CI 0.954 to 1.624, $P = .105$). While results from this trial clearly establish the activity of tivozanib in clear cell RCC, given the profusion of available agents targeting this pathway, further studies are required to define the optimal use of this agent in the context of the current treatment landscape.

Despite advances in our ability to target the VEGF pathway in a clinically meaningful manner, most patients with clear cell RCC eventually progress and die from their disease. Identifying mechanisms mediating both primary and acquired or adaptive resistance to VEGF pathway inhibition is an area of active investigation. Activation of alternative means of promoting and supporting angiogenesis in the face of VEGF inhibition has emerged as a possible contributor to resistance in preclinical models. Fibroblast growth factor (FGF) receptors (FGFR-1 and FGFR-2) have been proposed as important mediators of resistance following effective VEGF pathway inhibition in some models (Korc and Friesel, 2009; Welti

et al, 2011). A recent noncomparative phase II study evaluated the use of sunitinib and **nintedanib**, a small angiokinase inhibitor with activity against VEGFR-1, -2, and -3, PDGFR- α/β , FGFR-1, -2, and -3, RET, and Flt-3 (Eisen et al, 2013). Ninety-nine patients with advanced clear cell RCC who had not received prior systemic therapy were treated with either nintedanib or sunitinib in a 2:1 ratio until disease progression as defined by RECIST 1.1 or the onset of unacceptable drug-related adverse events. The primary end point was PFS at 9 months, as well as the incidence of significant Q-Tc interval change in the nintedanib group. **There was no significant difference in PFS at 9 months between the two groups (43% in the nintedanib arm vs. 45% in the sunitinib arm, $P = .85$).** Secondary efficacy end points were also similar between the two groups, including response rate (18.8% vs. 31.3%, $P = .19$), median OS (20.4 vs. 21.2 months, $P = .63$), and median time to progression (8.5 months in both groups). **Dovitinib**, an oral inhibitor of VEGFR, PDGFR, and FGFR, was studied in an open-label randomized phase III trial in patients with clear cell RCC who had received one prior VEGF and one prior mTOR therapy (Motzer, 2013). A total of 570 patients were randomized 1:1 to dovitinib or sorafenib with PFS as the primary end point. Most patients had received an anti-VEGF agent (92%) followed by an mTOR agent before enrolling in the trial. PFS was comparable, with a median of 3.7 and 3.6 months (HR 0.86, 95% CI 0.72 to 1.94, $P = .063$) in the dovitinib and sorafenib arms, respectively. Median OS (HR 0.96, 95% CI 0.75 to 1.22, $P = .357$) was also similar (11.1 and 11 months in the dovitinib and sorafenib arms, respectively). While the two aforementioned studies dampen enthusiasm for further evaluation of FGFR inhibitors in RCC, it must be noted that there was no attempt made in these studies to select patients based on evidence of FGFR pathway activation in their tumors. Additionally, no pharmacodynamic end points were reported, rendering it impossible to determine if effective FGFR-1 inhibition was achieved with either of these drugs.

Inhibitors of the Mammalian Target of Rapamycin

mTOR is a key intracellular protein that is a component of several signaling cascades, including those mediating the effects of some growth factors. It appears to play a role in regulating translation and stability of HIF-1 α , and preclinical models have suggested that growth inhibition occurring in response to mTOR inhibitors correlates with a block in HIF-1 α translation (Hudson et al, 2002; Thomas et al, 2006). Two analogues of sirolimus, **temsirolimus** and **everolimus**, have been clinically evaluated with demonstrable activity in RCC.

A phase II trial of **temsirolimus** evaluated three different doses (25 mg, 75 mg, and 250 mg per week administered intravenously) in 111 patients assigned randomly to one of the dose levels (Table 63-11). The overall response rate observed in this trial was modest (7%, including one patient with a complete response), and the median PFS was 15 months (Atkins et al, 2004). Responses and PFS appeared to be independent of temsirolimus dose. An exploratory subgroup analysis based on stratification of patients according to

TABLE 63-11 Summary of Selected Studies of mTOR Inhibitors in Metastatic Renal Cell Carcinoma

MSKCC risk groups revealed that patients in the poor-risk group had a longer median OS compared with historical controls receiving interferon- α (8.2 vs. 4.9 months). Based on this observation, a three-arm randomized phase III trial of 626 patients with three or more predefined poor-risk features was undertaken (Hudes et al, 2007). Patients with previously untreated metastatic kidney cancer of all histologic subtypes were eligible and randomized to receive temsirolimus alone (25 mg intravenously every week), interferon alfa alone (up to 18 million units subcutaneously three times a week), or temsirolimus (15 mg intravenously every week) plus interferon alfa (6 million units subcutaneously three times a week). PFS was superior in both temsirolimus-containing arms compared with interferon alone (median 3.8 vs. 1.9 months). Importantly, the trial also demonstrated a significantly higher OS in the temsirolimus arm compared with the interferon-only arm (median OS 10.9 vs. 7.3 months, $P = .008$), while the addition of temsirolimus did not appear to significantly alter OS compared with interferon alone (median OS 8.4 vs. 7.3 months, $P = .70$) (Fig. 63-9). Temsirolimus was fairly well tolerated, and most common adverse events such as mucositis, fatigue, rash, hyperglycemia, hypophosphatemia,

hypercholesterolemia, and pulmonary complications were amenable to medical and/or supportive measures. Based on these data, temsirolimus was approved by the FDA for the treatment of patients with metastatic RCC, and the agent is a reasonable frontline choice in patients presenting with poor-risk features.

Everolimus is an orally bioavailable inhibitor of mTOR. It was the subject of a phase III trial in patients with metastatic clear cell RCC whose disease had progressed after therapy with sunitinib, sorafenib, or both (Motzer et al, 2008b). Patients were randomized to receive either everolimus, 10 mg once daily ($n = 272$), or placebo ($n = 138$) (see Table 63-11). The trial was stopped after an interim analysis demonstrated superior PFS in the everolimus arm (median 4 months) compared with the placebo arm (median 1.9 months) (Fig. 63-10). At the time of this analysis, median survival had not been reached in the everolimus group and was 8.8 months for the placebo group; OS was not significantly different in the two groups. Although the agent offers only a modest improvement in PFS in patients progressing on first-line VEGFR antagonists, it is nonetheless a reasonable therapeutic option and has been approved by the FDA for this indication.

Figure 63-9. Kaplan-Meier estimates of overall survival in 626 metastatic renal cell carcinoma patients with adverse prognostic features randomized to receive temsirolimus alone, interferon- α alone, or combination therapy. (From Hudes G, Carducci M, Tomczak P, et al. Temsirolimus, interferon alfa, or both for advanced renal-cell carcinoma. *N Engl J Med* 2007; 356:2271–81.)

(From Motzer RJ, Escudier B, Oudard S, et al. Efficacy of everolimus in advanced renal cell carcinoma: a double-blind, randomised, placebo-controlled phase III trial. *Lancet* 2008;372:449–56.)

Combination and Sequential Therapy with Agents Targeting the von Hippel-Lindau Pathway

Combinations of two or more classes of agents with activity centered on different components of the VHL pathway provide an attractive strategy that might serve to increase efficacy as well as eliminating potential mechanisms of resistance. A major limitation of this approach is the overlapping toxicity profile of several drugs, necessitating significant dose reductions of individual drugs (Feldman et al, 2009; Patel et al, 2009). Several combinations of mTOR and VEGF pathway antagonists have been evaluated in phase I trials. In general, combinations of first-generation VEGFR inhibitors such as sunitinib with an mTOR inhibitor are associated with significant toxicity, discouraging their evaluation in phase II/III studies (Feldman et al, 2009; Patel et al, 2009). However, bevacizumab-based combinations appear to be better tolerated and have been evaluated in several trials.

The activity of bevacizumab in combination with everolimus was evaluated in a phase II trial of metastatic clear cell RCC patients (n = 80); both treatment-naïve patients (n = 50) and patients who had previously received sunitinib and/or sorafenib were eligible (Hainsworth et al, 2010). Median PFS in the treatment-naïve and previously treated populations was 9.1 and 7.1 months, respectively. The combination was further evaluated in a phase III trial (RECORD-2) that compared its efficacy to that of bevacizumab plus interferon- α (Ravaud et al, 2013). This study demonstrated similar median PFS, OS, and safety profiles in both groups, which suggests no additional advantage to replacing interferon- α with everolimus in combination with bevacizumab. The INTORACT trial compared the combination of either temsirolimus or interferon- α to bevacizumab (Rini et al, 2014). Seven hundred and ninety-one patients with previously untreated metastatic clear cell RCC were randomized to one of the aforementioned groups; the primary end point of the trial was PFS. There was no significant difference between the temsirolimus and interferon- α groups in median PFS (9.1 vs. 9.3 months, HR 1.1, 95% CI 0.9 to 1.3, $P = .80$), OS (25.8 vs. 25.5 months, HR 1.0, 95% CI 0.9 to 1.3, $P = .6$), or objective response rates (27.0% vs. 27.4%, risk ratio 1.0, 95% CI 0.8 to 1.3, $P = 1.0$). The combination of temsirolimus plus bevacizumab, however, appeared to be better tolerated, with superior symptom scores as assessed by the validated Functional Assessment of Cancer Therapy–Kidney Symptom Index (FKSI)-15 and FKSI-Disease Related Symptoms, without a significant difference in global health outcomes. Based on these studies, combinations of bevacizumab with an mTOR inhibitor do not appear to offer additional activity compared to established standard-of-care options in the first-line setting. Whether these combinations are substantively different from single-agent bevacizumab remains to be addressed.

Given the profusion of agents with single-agent activity in RCC, identifying the optimal sequencing of these agents is a question of considerable importance. A randomized study has demonstrated that everolimus can prolong PFS compared with placebo in patients who have progressed on first-line VEGFR antagonists (Motzer et al, 2008b). Smaller retrospective analyses have suggested that a proportion of patients who have progressed on one VEGF pathway inhibitor may benefit from a second agent targeting the same pathway (Rini et al, 2008b; Tamaskar et al, 2008).

A commonly employed treatment paradigm is to offer patients an mTOR inhibitor after disease progression on a first-line VEGFR–tyrosine kinase inhibitor, based on the RECORD-1 trial, which showed a longer PFS in patients treated with everolimus compared with placebo after failure of front-line VEGF therapy (Motzer et al, 2008b). This paradigm was further tested in the RECORD-3 trial, which addressed the issue of whether the sequence in which VEGF and mTOR pathway agents were administered might impact outcome (Motzer et al, 2013a). Four hundred and seventy-one patients with metastatic RCC (any risk category; 85.4% had clear cell histology) without prior systemic therapy were randomized to receive either first-line sunitinib or everolimus until disease progression, at which point they crossed over to the alternate drug. The

primary end point was to assess whether first-line everolimus resulted in a PFS that was not inferior to first-line sunitinib. Median PFS was significantly better in patients receiving first-line sunitinib (10.7 months, 95% CI 8.2 to 11.5) compared to those receiving everolimus as initial therapy (7.9 months, 95% CI 5.6 to 8.2, HR 1.43, range 1.15 to 1.77). At the time of the analysis, there was also a trend toward worse OS in the first-line everolimus group (median OS 22.4 months) versus the first-line sunitinib group, (32.0 months, HR 1.24, 95% CI 0.94 to 1.64). These data suggest that the standard sequence used commonly in clinical practice, particularly in patients with standard-risk disease (first-line VEGFR–tyrosine kinase inhibitor followed by mTOR agent upon disease progression) results in better outcomes than using an mTOR agent first.

Carefully designed clinical trials are required to identify the most effective strategies for sequencing multiple agents, as well as to categorize patients most likely to benefit from a given sequence based on molecular characterization of their tumors.

Other Treatment Options in Patients with Clear Cell Renal Cell Carcinoma

Chemotherapy

Conventional cytotoxic chemotherapy has been largely ineffective in the management of clear cell RCC. Numerous chemotherapeutic agents, including 5-FU, platinum compounds, gemcitabine, vinblastine, and bleomycin, have been evaluated as single agents in this disease but have failed to demonstrate clinically meaningful activity; a wide array of combination chemotherapy regimens have fared little better (Haas et al, 1976; Hahn et al, 1977; Zaniboni et al, 1989; Mertens et al, 1993, 1994; Amato, 2000; Rini et al, 2000, 2005; Stadler et al, 2006). Comprehensive meta-analyses of chemotherapy trials in RCC indicate the overall response rate is 5.5% to 6.0% (Yagoda et al, 1995). Although the mechanisms underlying this profound chemoresistance have not been fully elucidated, overexpression of the multidrug resistance gene (MDR) has been proposed as one possible culprit (Fojo et al, 1987). However, the addition of MDR inhibitors such as toremifene, cyclosporine, and verapamil to conventional chemotherapeutic agents has failed to improve their efficacy, suggesting that other, as yet unrecognized, factors may be at play (Braybrooke et al, 2000). Cytotoxic chemotherapy has no role in the current management of most patients with clear cell RCC. One situation in which chemotherapy may bear further investigation is in patients whose tumors demonstrate a sarcomatoid component; a small case series has suggested promising activity for gemcitabine-based chemotherapy in this setting, prompting further study of this approach (Nanus et al, 2004).

Hormonal Therapy

Hormonal therapy had been the subject of trials in RCC in the 1970s and 1980s, preceding the advent of cytokines. These studies were prompted both by the lack of effective therapies for kidney cancer and by the belief that a male preponderance (kidney cancer occurs approximately twice as frequently in males) implied a hormonal basis for this malignancy. Hormonal agents such as medroxyprogesterone have been noted to induce tumor regressions in a small minority of patients, but overall response rates are too low (approximately 2%) to have meaningful clinical impact in most patients (Harris, 1983; Schomburg et al, 1993; Medical Research Council Renal Cancer Collaborators, 1999; Braybrooke et al, 2000). Progesterational and other hormonal agents have no role in the current management of RCC.

SYSTEMIC THERAPY FOR NON-CLEAR CELL VARIANTS OF RENAL CELL CARCINOMA

Non-clear cell subtypes of kidney cancer are relatively rare (constituting approximately 15% to 25% of all kidney cancer) and have been the subject of few prospective studies. Given the unavailability

of agents of proven efficacy in papillary, chromophobe, and other rare histologic subtypes, patients with non-clear cell renal tumors often receive agents with activity in clear cell RCC.

VEGFR inhibitors active in clear cell RCC have only modest efficacy in papillary RCC. Sorafenib and sunitinib were shown to have minimal activity in retrospective studies of papillary RCC patients (Choueiri et al, 2008a). Prospective phase II trials with sunitinib have demonstrated that this agent is associated with low response rates (5% to 10%) in papillary RCC. The Southwest Oncology Group reported an 11% overall response rate with erlotinib, an oral epidermal growth factor receptor (EGFR) inhibitor, in 52 patients with metastatic papillary RCC with a 6-month PFS of only 29%.

An exploratory subgroup analysis of patients enrolled in a large randomized phase III study evaluating the efficacy of temsirolimus versus interferon in “poor prognosis” patients suggests that mTOR inhibitors may have activity in some non-clear cell variants. Approximately 20% of the patients enrolled in this trial had non-clear cell histologies (predominantly papillary RCC). The outcome of 37 patients with non-clear cell RCC treated with temsirolimus (both OS and PFS) was found to be better than that of 36 patients receiving interferon in this subgroup analysis. Although these data suggest that temsirolimus may have activity in some non-clear cell variants, these conclusions are limited by the fact that this is a subgroup analysis (Dutcher et al, 2009). Everolimus was evaluated in a relatively large open-label, multicenter phase II clinical trial as a first-line agent in patients with metastatic papillary RCC (RAPTOR); results from this trial were recently reported in abstract form (Escudier et al, 2013). At the time of a preliminary intent-to-treat analysis ($n = 83$), median PFS was 3.7 months (95% CI 2.4 to 5.5), while median OS was 21 months (95% CI 15.4 to 28) by independent radiology review. Common grade 3 or 4 adverse events included asthenia (10.6%), fatigue (5.4%), and anemia (5.4%). Around 27.2% of the patients discontinued treatment because of adverse events. A second phase II trial of everolimus in patients with

metastatic non-clear cell RCC was recently published (Koh et al, 2013). Of the 49 patients enrolled, 29 (59%) had papillary RCC and 23 (47%) had had prior anti-VEGF therapy. Partial response was noted in 5 (10%), stable disease in 25 (51%), and disease progression in 16 (32.7%) of the 49 patients. Interestingly, two of five patients with objective response to everolimus had chromophobe RCC, whereas two had papillary RCC and one had an unclassified RCC variant. The median PFS in this study was 5.2 months, and patients with chromophobe RCC had a trend toward longer PFS compared to other non-clear cell RCC patients ($P = .084$). Based on the two foregoing trials, everolimus appears to have modest activity in patients with papillary/non-clear cell RCC.

Recent advances in our understanding of the genetic and molecular alterations underlying several RCC subtypes have begun to lead to a more rational and individualized approach to their management. As with clear cell RCC, hereditary forms of papillary and chromophobe RCC hold the key to the identification of critical molecular events leading to these tumors in both familial and sporadic settings (Linehan, 2003; Linehan et al, 2009). Hereditary papillary renal cell carcinoma (HPRCC) is a familial condition characterized by the predisposition of affected individuals to develop bilateral, multifocal papillary type I RCC. HPRCC is characterized by the presence of activating germline mutations in the tyrosine kinase domain of the proto-oncogene *MET*, which is located on chromosome 7; this is usually accompanied by non-random duplication of the chromosome containing the mutated allele in the tumors (Schmidt et al, 1997, 1998, 1999, 2004; Zhuang et al, 1998; Linehan, 2003; Linehan et al, 2009). *MET* is a cell surface receptor that is normally activated on binding its ligand, hepatocyte growth factor (HGF), but is rendered constitutively active in the presence of mutations in the kinase domain of this protein (Bottaro et al, 1991; Dharmawardana et al, 2004; Peruzzi and Bottaro, 2006; Giubellino et al, 2009). The HGF/*MET* pathway is involved in regulating a variety of biologic functions, including cell growth, proliferation, and motility (Fig. 63-11) (Jeffers et al,

Figure 63-11. MET oncogenic signaling pathway. Important downstream biochemical and biologic consequences of MET activation, by hepatocyte growth factor (HGF) binding or by constitutive activation of the receptor tyrosine kinase activity by mutation, are represented. The MET ligand (HGF), MET tyrosine kinase activity, and downstream effectors (such as Grb-2) are potential targets for drugs in tumors with aberrant pathway activation. (From Peruzzi B, Bottaro DP. Targeting the c-Met signaling pathway in cancer. Clin Cancer Res 2006;12:3657–60.)

1998; Giubellino et al, 2009). Somatic MET alterations have been noted in a proportion of patients with sporadic papillary RCC, with activating mutations identified in approximately 13% of papillary tumors in one series. Gain of chromosome 7 (both *HGF* and *MET* are located on chromosome 7) has been described in more than two thirds of papillary tumors and may represent an alternative mechanism contributing to activation of the MET pathway in these tumors (Kovacs et al, 1991; Henke and Erbersdobler, 2002).

The realization that MET activation may play an important role in some forms of papillary RCC has led to the evaluation of foretinib, a novel tyrosine kinase inhibitor with activity against MET and VEGFR-2 in this RCC subtype. In a phase II study by Choueiri and colleagues (2013), two dosing regimens were evaluated in sequential patient cohorts: cohort A (n = 37) received an intermittent dosing regimen of 240 mg of foretinib given on days 1 through 5 of every 14-day cycle, and cohort B (n = 37) received a continuous daily dosing regimen of 80 mg/day. The primary end point was overall response rate based on RECIST. An overall response rate of 13.5% with a median PFS of 9.3 months was reported in the entire study population. A subgroup analysis was undertaken to determine if MET pathway activation was associated with treatment outcome. The presence of a germline *MET* mutation was associated with a high likelihood of response, with 5 of 10 patients (50%) demonstrating a PR in this group compared to 5 of 57 responders (9%) in the absence of germline alterations. The side effect profile for foretinib appeared similar to that of other anti-VEGFR agents, with hypertension being the most commonly reported adverse effect. Although the primary end point of overall response rate greater than 25% was not met, foretinib has activity in papillary RCC, notably in the germline *MET* mutation cohort, indicating that MET inhibition might be a viable treatment option for a subset of patients with papillary RCC.

A second form of hereditary papillary RCC is associated with alterations in the fumarate hydratase gene (*FH*), which encodes a tricarboxylic acid cycle enzyme that catalyzes the conversion of fumarate to malate. Germline *FH* mutations are seen in patients with hereditary leiomyomatosis and renal cell carcinoma (HLRCC), a condition associated with a highly aggressive variant of type II papillary RCC (Launonen et al, 2001; Lehtonen et al, 2006; Grubb et al, 2007; Merino et al, 2007; Linehan et al, 2010b). It has long been recognized that accumulation of fumarate, resulting from FH inactivation, leads to a VHL-independent upregulation of intracellular HIF and transcriptional activation of downstream proangiogenic and growth factors (Isaacs et al, 2005). Loss of FH activity promotes a metabolic shift in these tumors, characterized by disruption of the Krebs cycle and a consequent reliance on aerobic glycolysis to satisfy cellular bioenergetic requirements (Shuch et al, 2013). Investigators at the NCI have recently attempted to therapeutically exploit the exquisite sensitivity of this variant of papillary RCC to glucose deprivation (Yang et al, 2010). They hypothesized that a combination of bevacizumab (a monoclonal antibody to VEGF) and erlotinib (inhibitor of EGFR kinase activity) would severely constrain glucose delivery to the tumor microenvironment and disrupt critical cellular processes. The combination of bevacizumab and erlotinib is currently being evaluated in patients with metastatic papillary RCC, and interim data from this trial were recently presented (Stamatakis et al, 2013). This interim analysis

included the first 34 individuals enrolled, of whom 20 had sporadic papillary RCC and 14 had HLRCC-associated kidney cancer. Sixteen patients had received at least one prior systemic therapy regimen. The overall RECIST response rate was 32% (11 of 34) in the entire cohort, with a disease control rate (partial response and stable disease) of 65%. Partial responses were seen in 6 of 14 (43%) individuals with HLRCC and 5 of 20 (25%) individuals with sporadic papillary RCC. After a median follow-up of 10.7 months, median PFS was 10.5 months (95% CI 7.4 to 18.6). While these results are promising and suggest that the combination of bevacizumab and erlotinib is highly active in some forms of papillary RCC, further follow-up is required to clearly define the efficacy of this regimen in this population.

Cytotoxic chemotherapy has been used with modest success in collecting duct carcinoma, a rare kidney cancer variant with similarities to urothelial malignancies. In a series of 23 patients with metastatic collecting duct carcinoma, a response rate of 26% (including one complete response) was reported with a regimen comprising gemcitabine and carboplatin. Median PFS (7.1 months) and OS (10.5 months) were modest (Oudard et al, 2007). In summary, there is no standard approach of proven efficacy for most patients with non-clear cell RCC, although some promising approaches are being evaluated. Enrollment in suitable trials should be considered for all patients with non-clear cell RCC.

Conclusion

The adrenal glands are retroperitoneal endocrine organs that are unique from other retroperitoneal structures because of their embryology, anatomy, and the critical role they play in homeostasis. Physiologically, the adrenals are responsible for the production of mineralocorticoids, glucocorticoids, androgenic steroids, and catecholamines. The absence of both adrenal glands, without supplementation of these critical hormones, is not compatible with life. This chapter focuses on the surgical and radiographic anatomy of the adrenal glands (Fig. 64-1A to D).

ANATOMIC RELATIONSHIPS

The adrenal glands are paired organs located cephalad to the kidneys in the retroperitoneum. The position of these glands varies from right to left. Both are located at the level of the 11th or 12th ribs, with the right gland located more superiorly and the left gland extending as low as the first lumbar space. The adrenals are enclosed within the perirenal (Gerota) fascia and are completely surrounded by perirenal adipose tissue. Each gland is separated from the upper pole of the ipsilateral kidney by a thin layer of connective tissue. Grossly, the adrenals are yellow-orange and are noticeably more orange than the surrounding adipose tissue. The dimensions of the glands range from 2 to 3 cm in width and are 4 to 6 cm in length (Mitty, 1988). The weight of each gland is approximately 5 g, and the weight ranges from 2 to 6 g with no variation between genders (Mills, 2007).

SURGICAL LANDMARKS

Dorsolaterally, the adrenal glands are in close proximity to the crus of the diaphragm. The right gland is triangular and is located nearly directly cranial to the upper pole of the right kidney. The adjacent structures include the underside of the liver anterolaterally, the duodenum anteromedially, the lateral margin of the inferior vena cava (IVC) medially, and the psoas muscle posteriorly (Fig. 64-2, top left). The left adrenal gland is more crescentic in shape and its lateral surface is in contact with the medial aspect of the upper pole of the left kidney. The adjacent structures include the splenic vessels and body of the pancreas anteriorly, the aorta medially, and the psoas muscle posteriorly (Fig. 64-2, bottom right).

The anatomic relationships between the adrenal glands and the surrounding intra-abdominal and retroperitoneal organs are important when considering a surgical approach. The cross-sectional anatomy of the adrenal gland (Fig. 64-3) demonstrates the relationship of the right adrenal gland with the liver and IVC, and the left adrenal gland relates to the splenic vasculature and the pancreas.

ADRENAL VASCULATURE

The vasculature of the adrenal glands is unique because the arterial and venous anatomy is highly variable. The arterial supply to the adrenal originates from three sources (Fig. 64-4). Superiorly, the adrenal is typically supplied by the inferior phrenic artery, and rarely by the aorta, celiac axis, or intercostal arteries. The middle adrenal artery typically arises from the lateral aspect of the aorta and rarely from the inferior phrenic artery or renal artery. The inferior adrenal artery typically arises from the superior aspect of the ipsilateral renal artery (Toni and Mosca, 1988). The three main adrenal arteries each branch into cascades of 10 to 50 smaller arteries that then penetrate the adrenal capsule.

There are three patterns of blood distribution within the adrenal gland (Fig. 64-5). Capsular arteries only supply the adrenal capsule and do not penetrate more deeply into the tissue. Fenestrated cortical sinusoidal capillaries supply the cortex and then drain into fenestrated medullary capillary sinusoids. Medullary arterioles travel within the trabeculae of the adrenal gland to deliver blood to the medullary capillary sinusoids. The medulla has two blood supplies: arterial blood from the medullary arterioles and venous blood from the cortical sinusoid capillaries that have already supplied the adrenal cortex with arterial blood (Ross et al, 1995). This dual vascular supply is important for the medullary production of catecholamines. As venous blood from the adrenal cortex reaches the medullary tissue, it contains a high concentration of glucocorticoids, and this situation plays a role in epinephrine synthesis (Bloom and Fawcett, 1986). The complex vascular supply to the adrenal gland is composed of the cortical vascular supply (cortical sinusoids draining into the medullary capillaries, and the medullary vein) and the medullary vascular supply (medullary arterioles and cortical sinusoids) (Gray et al, 1995).

The venous drainage of the adrenals varies by side, although both adrenal glands are drained by a single central vein that exits

Figure 64-3. Cross-sectional anatomy of the adrenal glands and their relationships to nearby structures. IVC, inferior vena cava. (Modified from Mitty HA. Embryology, anatomy, and anomalies of the adrenal gland. *Semin Roentgenol* 1988;23:271–9.)

Figure 64-4. Arterial supply to the adrenal glands. (From Drake RL, Vogl W, Mitchell AWM. *Gray's anatomy for students*. Philadelphia: Elsevier; 2005.)

the adrenal anteromedially, with emissary veins connecting the central vein to the pericapsular adrenal arterial plexus (Mitty, 1988). The right adrenal vein is short and enters the posterior aspect of the IVC. The longer left adrenal vein joins with the inferior phrenic vein and enters the cranial aspect of the left renal vein (Fig. 64-6) (Avisse et al, 2000).

ADRENAL NERVES

Innervation of the adrenal gland is important for release of catecholamines from the chromaffin cells of the medulla (Fig. 64-7). Preganglionic sympathetic nerve fibers from the lower thoracic and lumbar spinal cord travel through the sympathetic chain to

reach a nerve plexus at the adrenal capsule. These nerves then traverse the cortex to reach the medulla (Bloom and Fawcett, 1986). The secretory products released from the adrenal medulla enter systemic circulation via fenestrated capillaries (Ross et al, 1995). Cholinergic innervation of the adrenal cortex has also been described, although it is not as well characterized as the innervation of the medulla (Charlton et al, 1991).

EMBRYOLOGY

The processes involved in the development of the adrenal glands were hypothesized until 1911 when the anatomy of adrenal glands from various stages of human development was initially described.

Figure 64-5. The complex vascular supply of the adrenal gland. (From Gray H, Williams PL, Bannister LH. *Gray's anatomy: the anatomical basis of medicine and surgery*. New York: Churchill Livingstone; 1995.)

Figure 64-6. Venous drainage of the right and left adrenal glands. The right adrenal vein enters the posterior aspect of the inferior vena cava. The left adrenal vein joins with the inferior phrenic vein and enters the cranial aspect of the left renal vein. (From Vaughan ED Jr, Carey RM, editors. *Adrenal disorders*. New York: Thieme Medical; 1989.)

The original illustration of the human fetal adrenal gland described an early fetal zone composed of immature cortical cells and groups of sympathogonia (Malendowicz, 2010). The fetal zone is an important part of development, and after birth this portion of the adrenal dramatically decreases in size.

The development of the adrenal gland begins at approximately the third or fourth week of fetal development, when columns of coelomic epithelium start to condense. During the next 2 weeks, these cells proliferate and begin to migrate to the cranial end of the mesonephros to form the adrenogonadal ridge, the common precursor to both the adrenals and the gonads. The adrenal cortex arises from the cephalic portion of the ridge, whereas precursor cells of the future gonads arise from the caudal portion of the ridge (Fig. 64-8).

Morphologic differentiation into a definitive zone and a fetal zone occurs between 8 and 10 weeks' development. Mesenchymal cells surrounding the fetal cortex form the adrenal capsule, and neural crest-derived cells migrate to the medial region to form the eventual adrenal medulla. At this time, blood vessels and nerves of the adrenal gland develop.

At birth the adrenal glands are relatively large and weigh twice the weight of the adult glands (Kempná and Flück, 2008). The fetal zone involutes during the first year of life, and is replaced by the definitive zone. This zone develops into the adrenal cortex regions named the zona glomerulosa (ZG) and the zona fasciculata, under the influence of adrenocorticotropic hormone secreted by the pituitary gland. With regression of the fetal zone, chromaffin cells that were scattered throughout the fetal zone aggregate to form the adrenal medulla (Ross et al, 1995). The medulla is homologous to a sympathetic ganglion without postganglionic processes. The zona reticularis (ZR), located between the zona fasciculata (ZF) and the medulla, is a relatively minor component of the adrenal cortex until early childhood. Between 6 and 8 years of life, the ZR expands to its adult volume (Sucheston and Cannon, 1968; Havelock et al, 2004; Else and Hammer, 2005; Kempná and Flück, 2008).

Several unique clinical findings occur with the aberrant development of the adrenal glands and neighboring structures. The

Figure 64-7. Innervation of the adrenal glands. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

Figure 64-8. Development of the adrenal gland. Note the close relationship between the gonadal ridge and the developing adrenal gland. (From Barwick TD, Malhotra A, Webb JA, et al. *Embryology of the adrenal gland and its relevance to diagnostic imaging*. Clin Radiol 2005;60: 953–9.)

developing kidneys ascend from the pelvis to unite with the adrenal glands at approximately 8 weeks of development (Moore and Persaud, 1998). In the setting of renal agenesis, the adrenal glands are found in their orthotopic positions, but they might be discoid instead of their normal triangular or crescent shapes (Mitty, 1988). Adrenal rests are ectopic tissue derived from either adrenal cortex or medulla. Adrenal rests are found in 1% of adults, and are typically located in the vicinity of the adrenals in proximity to the celiac axis (Graham, 1953). These rests can also be found along the path of gonadal descent. Adrenal rests associated with the gonad are found in 7.5% to 15% of neonates, and they usually regress with time (Graham, 1953). In cases of congenital adrenal hyperplasia, these rests can sometimes present as testes masses. The clinical significance of ectopic adrenal tissue may be important for compensatory hypertrophy after adrenalectomy, inadvertent excision of a heterotopic adrenal gland during unrelated surgery, or neoplastic transformation (Schechter, 1968).

HISTOLOGY

The adult adrenal gland consists of an outer cortex, which makes up approximately 90% of the adrenal mass, and an inner medulla. The gland is surrounded by a capsule composed of hypocellular fibrous tissue [(Mills, 2007). The adrenal cortex consists of three concentric zones (Fig. 64-9): the outer ZG comprising approximately 15% of the cortex, the middle ZF, which includes 80% of the cortex, and the inner ZR including 5% to 7% of the cortex (Ross et al, 1995). The zones are distinct and each is identifiable by the typical appearance of the cells and the ultrastructure of the cellular arrangements.

The ZG is composed of small, polyhedral cells arranged in ovoid clusters and curved columns, which are surrounded by sinusoidal capillaries. The cells are notable for less abundant cytoplasm and a large amount of lipid in the cytoplasm, which results in a vacuolated appearance. These cells are characterized by a higher nuclear-to-cytoplasmic ratio. Aldosterone is synthesized in these cells in the smooth endoplasmic reticulum and the mitochondria (Bloom and Fawcett, 1986; Ross et al, 1995; Cormack, 1998; Mills, 2007). The ZF, which is the largest of the three cortical zones, contains large pale polyhedral cells arranged in long straight cords, separated by capillaries. These cells contain a higher amount of lipid than the other zones, and they are referred to as “clear cells” because of their histologic appearance (Mills, 2007). The ZR is composed of smaller cells arranged in anastomosing cords.

Figure 64-9. Cross-sections through the infant and adult adrenal gland. (From Bloom W, Fawcett DW. *Bloom and Fawcett: textbook of histology*. Philadelphia: Saunders; 1986.)

The adrenal medulla is composed of chromaffin cells arranged in ovoid clusters and cords. This portion of the adrenal gland provides 10% of the weight and volume of the total adrenal gland (Mills, 2007). The medullary cells are large and epithelioid in appearance, and they are closely associated with medullary capillaries. They are often poorly outlined and are arranged in vague clusters with nuclei of varying sizes (Mills, 2007). Chromaffin cells are postganglionic sympathetic neurons that have lost their axons and dendrites (Paulsen, 1996). Staining and electron microscopy of these cells can differentiate between those that secrete epinephrine and those that secrete norepinephrine (Bloom and Fawcett, 1986).

RADIOLOGY

Several imaging modalities are used to image the adrenal gland and its pathology. These include computed tomography (CT), magnetic

Figure 64-10. Radiographic images of the adrenal glands. A, Axial computed tomography (CT) image of abdomen with arrow indicating right adrenal gland. D, Ultrasound image of right upper quadrant with arrow indicating right adrenal gland.

resonance imaging (MRI), ultrasonography (US), angiography, metaiodobenzylguanidine scan, and positron emission tomography. Adrenal imaging is beneficial for the evaluation of abnormal adrenal morphology or function, and it is discussed in further detail in other chapters. This section reviews normal adrenal anatomy using CT, MRI, US, and angiography.

Computed Tomography

CT is the most widely used imaging modality for imaging the adrenal glands. The perinephric adipose tissue allows for clear visualization of the adrenal gland with outstanding resolution. Although CT provides excellent morphologic information, it does not provide functional data. On axial sections, the adrenal glands present the appearance of an inverted “V” or “Y.” The limbs of the normal adrenal gland are usually thinner than the adjacent diaphragmatic crura, with a width of approximately 3 to 6 mm. The right adrenal gland lies just superior to the upper pole of the right kidney and posterolateral to the IVC (Fig. 64-10A). The left adrenal gland is slightly more caudal and lies anterior and medial to the upper pole of the left kidney and posterior to the splenic vessels (Fig. 64-10B). Normal adrenal tissue has a density of less than or equal to 10 Hounsfield units (HU) on noncontrast CT imaging.

Magnetic Resonance Imaging

MRI of the adrenal glands is slightly inferior to CT in terms of spatial resolution, but MRI is a useful adjunct in selected cases of abnormal pathology. Coronal or sagittal images may confirm the adrenal origin of a mass when axial images are equivocal. Contrast resolution of MRI, via T1-weighted and T2-weighted images, is superior to that of CT and enables differentiation of adrenal masses. The technique of flow-related enhancement allows excellent evaluation of the arterial and venous vasculature. The transverse imaging plane is most commonly used to evaluate the adrenal gland at an MRI slice thickness of less than or equal to 3 mm. On T1-weighted images, the normal adrenal gland has a uniform

intermediate signal intensity that is slightly less intense than that of the liver and renal cortical tissue (Fig. 64-10C). On T2-weighted images, the normal adrenal gland is difficult to distinguish from retroperitoneal adipose tissue because of the presence of intracellular lipid within the gland.

Ultrasonography

US imaging of the adrenal glands is typically performed to identify abnormalities. When the normal adrenal glands are visualized with this modality, they appear as hypoechoic structures (Fig. 64-10D). The retroperitoneal adipose tissue can make it difficult to differentiate normal adrenal tissue from the surrounding structures. As a result, US imaging is more commonly used for differentiating between solid and cystic masses of the adrenal gland.

Angiography

Adrenal venous sampling is performed to provide functional information by obtaining blood samples for metabolic assay. Inferior vena cavography can be performed to evaluate the intraluminal component of an adrenal malignancy when CT, MRI, and US are equivocal. Adrenal arteriography is rarely performed or required, because CT and MRI nearly always provide the essential morphologic information required for surgical planning.

CONCLUSION

The adrenal glands have unique anatomic, embryologic, and histologic characteristics. The adrenal gland's anatomic and histologic transformation from fetal development through adulthood is unlike any other organ. An appreciation of their vascular and anatomic relationships is critical both for surgical approaches to the adrenal glands and also to nearby organs. As radiographic imaging of the adrenal glands has evolved, normal and pathologic adrenal anatomy can be better characterized.

KEY POINTS

- Embryologically, the adrenals are distinct from the kidneys, and developmental abnormalities of one organ do not affect the other.
- The adrenal gland is divided into the cortex and the medulla.
- The adrenal cortex is composed of three distinct areas: the ZG, the ZF, and the ZR.
- The adrenal medulla receives preganglionic sympathetic input that stimulates the release of catecholamines from the medullary chromaffin cells.
- Arterial supply to the adrenals arises from branches of the inferior phrenic artery, aorta, and renal artery.
- Venous drainage of the adrenals varies by side, with the right adrenal vein entering the IVC and the left adrenal vein entering the left renal vein.

Historical Background

Adrenal Anatomy and Embryology

Adrenal Physiology

Adrenal Disorders

Evaluation of Adrenal Lesions in Urologic Practice

Conclusions

The adrenal glands are small and deceptively simple. Formerly known as the *suprarenal glands*, given their location above the kidneys, this paired triangular organ sits at an anatomic crossroads in the upper abdomen adjacent to major vessels, nerves, and other vital organs, which the adrenal glands help to monitor and regulate. The complexities of adrenal endocrine and neurocrine function only recently have been more fully recognized. Indeed, **adrenals are now known to be central to homeostasis**. Moreover, pathology involving the glands is responsible for major human ailments.

Given the varied systemic adrenal functions and dysfunctions, medical management is primarily within the purview of endocrinologists, nephrologists, and cardiologists. Similarly, surgical management of adrenal diseases historically has been divided among urologists, general surgeons, surgical oncologists, and, more recently, endocrine surgeons, with referral patterns often dependent on traditions established at individual institutions (Simhan et al, 2012b). With the urologist's advanced minimally invasive surgical skills, comfort with both retroperitoneal anatomy and surgical approaches to retroperitoneal organs, and the close relationship between renal and adrenal pathophysiology, **it is natural that the evaluation and surgical management of adrenal disorders remain firmly in the domain of practicing urologic surgeons.**

HISTORICAL BACKGROUND

The diminutive adrenal glands were easily overlooked by early physicians. Distinguished anatomists such as Galen, da Vinci, and Vesalius omitted the adrenal glands in their descriptions of the retroperitoneum. Bartholomaeus Eustachius was the first to describe the organs in the mid-16th century (Scott, 1990). Not until the mid-19th century was the critical importance of the adrenal recognized when Thomas Addison, an English physician, described a series of patients with the condition of **adrenal insufficiency** that now carries his name. He linked the disease to the adrenal glands on careful inspection of the organs at autopsy (Addison, 1855). Soon thereafter, Charles Brown-Séquard, through a series of animal experiments, demonstrated that **bilateral adrenalectomy uniformly resulted in death**, suggesting that the adrenals were indispensable to the survival of the host (Brown-Séquard, 1856). William Osler was the first to report treatment of Addison disease with hormonal replacement in 1896. He administered crude extract from the adrenal glands of pigs to a patient with Addison disease and produced significant weight gain in this one individual (Oliver and Sharpey-Schafer, 1895). In the ensuing half-century, "adrenalin"

was discovered, and its production was localized to the adrenal medulla (Oliver and Sharpey-Schafer, 1895). The ability of adrenalin to produce a sustained rise in blood pressure was subsequently determined (Abell and Crawford, 1897). Moreover, the failure of this substance, later termed "epinephrine," to sustain life after bilateral adrenalectomy underscored the complexity and multifunctionality of the adrenal gland and established Addison disease as an ailment of the adrenal cortex (Scott, 1990; Porterfield et al, 2008). Discovery and isolation of cortisol from the adrenal gland in the 1930s and subsequent work on its use to treat rheumatoid arthritis produced a 1950 Nobel Prize in Physiology or Medicine for Edward Kendall, Philip Hench, and Tadeus Reichstein (Scott, 1990). Aldosterone was ultimately isolated from the bovine adrenal in 1952 (Grundy et al, 1952). The latter part of the 20th century witnessed a rapid transformation in our understanding and treatment of adrenal disorders led by pioneers such as Jerome Conn, Lawson Wilkins, Grant Liddle, and Earl Sutherland (Scott, 1990).

ADRENAL ANATOMY AND EMBRYOLOGY

Overview

The adrenal glands are paired retroperitoneal organs composed of a cortex and medulla. Gross examination reveals a distinct spiculated mustard-yellow-colored cortex that is distinct from the surrounding perinephric fat and the inner medulla, which can be distinguished macroscopically on cross section by its central brown color (see Figs. 65-1 and 65-2 on the Expert Consult website). The normal adrenal glands weigh an average of 4 to 5 g each and range in size from 4 to 6 cm in length and 2 to 3 cm in width (Mitty, 1988; Silverman and Lee, 1989; Avisse et al, 2000). Morphologically, the right adrenal gland is triangular, whereas the left adrenal gland is crescent-shaped (Avisse et al, 2000). They may sit either immediately superior to the kidney, "capping" the upper pole, or superior medially to the upper pole, "cradled" by the kidney just above the renal vessels. Once understood, this difference can be appreciated through either computed tomography (CT) scan or magnetic resonance imaging (MRI) and is a relevant surgical distinction, particularly in patients with substantive perinephric fat and on the left side when identifying the adrenal vein.

Embryology

The adrenal cortex and the medulla are two embryologically and functionally distinct units. The cortex is derived from the intermediate mesoderm of the urogenital ridge (Mitty, 1988; Barwick et al,

Figure 65-1. Adrenal vascular supply demonstrating inflow from the superior, middle, and inferior adrenal arteries bilaterally. Whereas the right adrenal vein drains directly into the posterior inferior vena cava, the left adrenal vein will often communicate with the inferior phrenic vein before draining into the left renal vein. (Courtesy the University of Kentucky.)

Figure 65-2. Normal adrenal gland histology. Macroscopic and low-power microscopic views of the adrenal cortex and medulla. The three layers of the adrenal medulla (glomerulosa, fasciculata, and reticularis) produce mineralocorticoids (aldosterone), glucocorticoids (cortisol), and sex steroids (adrenal androgens and estrogens), respectively. The acronym *GFR = ACE* summarizes this relationship (glomerulosa, fasciculata, reticularis = aldosterone, cortisol, estrogen) nicely. (Courtesy Dr. Thomas J. Sebo, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.)

2005). Beginning in the 5th week of gestation, mesenchymal cells located at the urogenital ridge and the root of the mesentery proliferate and form the cortex of the fetal adrenal gland. During the 6th and 7th weeks of gestation, additional mesothelial cells surround the fetal adrenal cortex, which will later form the adult adrenal cortex (Mitty, 1988; Barwick et al, 2005). By the end of the 8th week of gestation the mesothelial cells forming the cortex are encapsulated by connective tissue and have separated from the peritoneal mesothelium. In distinction, the adrenal medulla is derived from neural crest cells, located in adjacent sympathetic ganglia, which migrate into the medial aspect of the fetal adrenal cortex by the 9th week of gestation (Kempna and Fluck, 2008). The neural crest cells continue to invade the adrenal cortex until they achieve a central position surrounding the adrenal vein by the 18th week of gestation. This embryologic relationship explains the brown stippling of the adrenal cortex.

At birth, the fetal adrenal gland is twice the weight of an adult adrenal gland but has not completed development. After birth, the fetal cortex begins to atrophy and will be completely resorbed by 12 months of age (Mitty, 1988). As the fetal cortex is being resorbed, the zona glomerulosa and fasciculata of the adult cortex continue to develop, but the zona reticularis will not complete differentiation until 3 years of age, reflecting the relative late importance of sex steroid production by this part of the adrenal cortex (Barwick et al, 2005; Kempna and Fluck, 2008).

Cases of unilateral adrenal agenesis are rare and are often associated with unilateral renal agenesis (Nakada et al, 1988; Else and Hammer, 2005). However, because adrenal and renal development are separate processes, this association is likely spurious and is the result of limited radiographic evaluation of the ipsilateral adrenal gland in cases of renal agenesis. **Most often, adrenal gland development occurs normally in the absence of ipsilateral renal unit development, malrotation, or malascence. In these cases, the adrenal glands are often discoid in shape and located in their normal position within the retroperitoneum (Mitty, 1988).**

More common anomalies of adrenal gland development include accessory adrenal tissue and adrenal heterotopia. Accessory renal tissue, also known as *adrenal rests*, can be composed of cortical or medullary tissues. Owing to the close proximity of the adrenal gland and genitourinary organ development, adrenal rests can be found anywhere along the path of gonadal descent within the retroperitoneum. Although adrenal rests can be found in up to 50% of neonates, the tissue typically atrophies and is found in only approximately 1% of adults (Barwick et al, 2005). In cases of congenital adrenal hyperplasia (CAH), adrenal rest within the testis may become hyperplastic and manifest as a testicular mass. This is an important consideration before performance of an orchiectomy for a testicular mass in patients with CAH. Adrenal heterotopia results from incomplete separation of primitive adrenal mesoderm from adjacent organs such as the liver or kidney, resulting in partial or complete incorporation of the gland into the adjacent organ.

Anatomy

The right and left adrenal glands are located within the Gerota fascia at the levels of the 11th and 12th ribs and share several important anatomic relationships, including being located cephalad to the upper pole of the kidneys and anterior to the crus of the diaphragm. The right adrenal is bounded medially by the inferior vena cava (IVC) and anteriorly by the liver; the left adrenal gland is bounded medially by the aorta and anteriorly by the stomach, pancreas, and splenic vessels. The close juxtaposition of these organs to the adrenal explains why lesions of adjacent organs, such as leiomyomas of the greater curvature of the stomach, may be confused for an adrenal mass.

As with most endocrine organs, the blood supply to the adrenal gland is redundant. Although variable, the arterial supply of each adrenal gland may arise from three main sources: superior adrenal arteries (branches from the inferior phrenic arteries), middle adrenal arteries (direct visceral branches from the aorta), and inferior adrenal arteries (branches from the ipsilateral renal artery (see Fig.

65-1). The main adrenal arteries then branch to form a subcapsular plexus. From the subcapsular plexus some branches continue directly to the medulla, and others form sinusoids supplying the adrenal cortex. On the venous side, medullary veins coalesce to form the adrenal vein, which is surrounded by medullary tissue within the adrenal gland. The short right adrenal vein drains directly into the vena cava. On the left, the adrenal vein is long compared with the right and is joined by the inferior phrenic vein before draining into the left renal vein. The overlapping of both arterial and venous anatomy makes partial adrenalectomy possible with little risk of subsequent adrenal infarction. The principal lymphatic drainage of the adrenal glands is through the paracaval lymph nodes on the right and the para-aortic lymph nodes on the left.

The autonomic innervation of the adrenal glands includes predominantly preganglionic sympathetic fibers off the sympathetic trunk directly to the chromaffin cells of the adrenal medulla, whereas postganglionic fibers originating from the splanchnic ganglia provide innervation to the adrenal cortex. Parasympathetic innervation to the adrenal cortex and medulla is not well defined; however, animal models suggest that parasympathetic branches originating from the vagus nerve may be present.

Histology

Each adrenal gland is enclosed within a fibrous capsule (see Fig. 65-2). Directly beneath the capsule is the cortex, which consists of three zones: the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa consists of small polyhedral cells with scant eosinophilic cytoplasm and dark round nuclei. The essential function of the glomerulosa is the production of mineralocorticoids, predominantly aldosterone. The broad layer of large pale cells arranged in vertical columns beneath the zona glomerulosa is the zona fasciculata responsible for the production of glucocorticoids such as cortisol. The zona reticularis, the innermost layer of the cortex, consists of round dark-staining cells and predominantly produces sex steroids, such as adrenal estrogens and androgens (Mitty, 1988; MacLennan et al, 2003) (Table 65-1).

KEY POINTS: ANATOMY AND EMBRYOLOGY

- The adrenal glands are composed of two embryologically and functionally distinct components: the cortex and the medulla (the former endocrine, the latter neurocrine).
- The arterial supply of the adrenal glands is variable and can arise from several sources. However, the venous drainage is more predictable, with the right adrenal vein emptying into the IVC and the left adrenal vein draining into the left renal vein in the majority of patients.

ADRENAL PHYSIOLOGY

Other than their juxtaposed anatomic associations, the adrenal cortex and the adrenal medulla are best conceptualized as two distinct organs, the former endocrine and the latter neurocrine.

Adrenal Cortex Physiology

As part of a multistep synthetic pathway, numerous enzymes of the adrenal cortex catalyze conversion of essential steroid hormones from the common precursor cholesterol. Low-density lipoprotein (LDL) serves as the primary source of cholesterol for the adrenals (Arlt and Stewart, 2005). **Ratios and types of enzymes in each zone of the adrenal cortex vary, resulting in different hormonal products for each region (Fig. 65-3) (Rainey, 1999).**

Steroid hormone receptors are absent on cellular membranes of target tissues. Instead, steroids diffuse passively into the cell and bind to their respective receptors intracellularly. Gene transcription is then modulated by direct binding of the hormone receptor

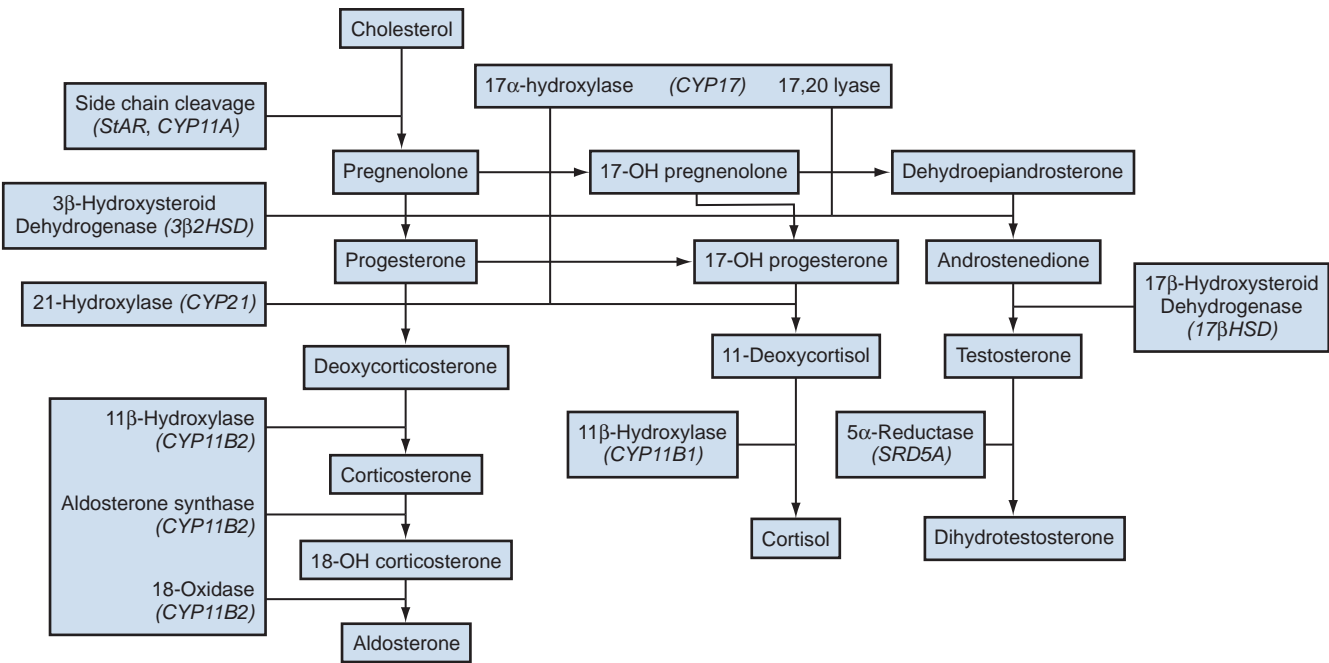

Figure 65-3. Steroid hormone synthesis beginning with cholesterol and resulting in mineralocorticoid, glucocorticoid, and androgen production in the adrenal cortex. Enzymes are listed in boxes and genes in parentheses. (From Hyun G, Kolon TF. A practical approach to intersex in the newborn period. *Urol Clin North Am* 2004;31:435–43.)

TABLE 65-1 Primary Effects of Mineralocorticoids

ACTION	EFFECT	SITE OF ACTION
Renal sodium reabsorption	Increased blood volume Increased blood pressure Decreased urine sodium	Distal tubule Connecting segment Collecting duct
Renal chloride reabsorption	Increased serum chloride Decreased urine chloride	Distal tubule Connecting segment Collecting duct
Renal potassium secretion	Decreased serum potassium Increased urine potassium	Distal tubule Connecting segment Collecting duct
Renal proton secretion	Increased urine NH ₄	Collecting duct—a result of sodium reabsorption

NH₄, ammonia.

complex to target DNA (Arlt and Stewart, 2005). As discussed previously, the three main zones of the adrenal cortex are the zona glomerulosa, zona fasciculata, and zona reticularis, with each zone primarily responsible for mineralocorticoid (100 to 150 µg/day), glucocorticoid (10 to 20 mg/day), and androgen synthesis (>20 mg/day), respectively (Arlt and Stewart, 2005).

Zona Glomerulosa

The zona glomerulosa is the outermost region of the adrenal cortex and is the only zone of the adrenal gland that contains

the enzyme aldosterone synthase (CYP11B2). As a result, the glomerulosa cells of this tissue are the sole source of aldosterone—the primary human mineralocorticoid (Rainey, 1999). Aldosterone regulates electrolyte metabolism by stimulating epithelial cells of the distal nephron to reabsorb Na⁺ and Cl[−], while secreting H⁺ and K⁺. Although aldosterone levels have a profound effect on total body Na⁺, concentration of the ion does not change, whereas reabsorption of sodium is accompanied by reuptake of free water. Therefore aldosterone primarily affects total body volume and not sodium concentration (White, 1994; Arlt and Stewart, 2005). Electrolyte balance in epithelial cells of the submaxillary salivary glands and the large intestine are also under mineralocorticoid control; however, the physiologic importance of this phenomenon is likely minimal (Bastl and Hayslett, 1992).

Aldosterone levels are primarily regulated by angiotensin II through the renin-angiotensin-aldosterone system (RAAS) and directly by serum potassium levels. A rise in adrenocorticotrophic hormone (ACTH) can also increase aldosterone secretion, but this is a much less potent stimulus (White, 1994; Arlt and Stewart, 2005). For this reason the zona glomerulosa is the only region of the adrenal cortex that does not atrophy on pituitary failure (Hubbard et al, 1990). Atrial natriuretic peptide is the main inhibitory regulator of aldosterone secretion, providing an important link among cardiac, adrenal, and renal function—although somatostatin, dopamine, and others may also play a role (Spat and Hunyady, 2004). A working knowledge of the RAAS is critical in conceptualizing and managing hyperaldosteronism. The pathophysiology of this pathway is discussed in the section on Conn syndrome.

Zona Fasciculata

The zona fasciculata is the site of glucocorticoid production as a result of zonal expression of 17α-hydroxylase, 21-hydroxylase, and 11β-hydroxylase enzymes (see Fig. 65-3) (Arlt and Stewart, 2005). Cortisol is the primary glucocorticoid in humans, and its secretion is under tight control of the ACTH. Accordingly, cortisol and ACTH are a part of a classic hormonal negative feedback system that features the hypothalamus, the pituitary gland, and the adrenal glands. The physiology of this axis is discussed in more detail in the

TABLE 65-2 Primary Effects of Glucocorticoids

EFFECTS	CLINICAL IMPLICATIONS
Enhance skeletal and cardiac muscle contraction	Absence results in weakness.
Cause protein catabolism	Excess results in muscle wasting and weakness.
Inhibit bone formation	Excess decreases bone density.
Inhibit collagen synthesis	Excess causes thin skin and fragile capillaries.
Increase vascular contractility and decrease permeability	Absence makes it difficult to maintain blood pressure.
Have anti-inflammatory activity	Exogenous steroid is useful in treating inflammatory diseases.
Have anti-immune system activity	Exogenous steroids are useful in promoting transplant tolerance and in treating autoimmune disorders.
Maintain normal glomerular filtration rate	Absence reduces glomerular filtration rate.

From Howards SS, Carey RM. The adrenals. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. 2nd ed. Chicago: Year Book; 1991.

section on Cushing syndrome (Jacobson, 2005). Production of cortisol by the adrenal glands follows a strict circadian schedule, with the majority of the hormone being secreted in the early morning (Jacobson, 2005). Glucocorticoids are essential to life and modulate complex physiologic pathways that include metabolism, immunity, maintenance of intravascular volume, regulation of blood pressure, and complex modulation of the central nervous system with significant effects on mood, sleep, and potentially memory (Arlt and Stewart, 2005) (Table 65-2).

Zona Reticularis

The zona reticularis is the innermost zone of the adrenal cortex. The presence of 17 α -hydroxylase and 17,20-lyase results in the production of dehydroepiandrosterone (DHEA), sulfated DHEA (DHEA-S), and androstenedione to this region, although some androgen synthesis also occurs in the zona fasciculata. Adrenal androgen secretion appears to be under control of ACTH, and, like cortisol, exhibits circadian patterns (Arlt and Stewart, 2005). DHEA, DHEA-S, and androstenedione comprise the greatest portion of steroid hormone that is produced by the adrenals (>20 mg/day), but appear to be the least important for adult physiologic homeostasis (Nguyen and Conley, 2008); however, pharmacologic manipulation of adrenal androgen production remains a viable and increasingly targeted strategy for advanced prostate cancer (see Chapter 121). Moreover, aberrations in production of these hormones during development are responsible for significant pathology and result in the clinical entity known as *congenital adrenal hyperplasia* (Finkelstein and Shaefer, 1979; Hubbard et al, 1990). CAH is discussed in detail in Chapter 150.

Adrenal Medulla Physiology

The adrenal medulla comprises less than 10% of total adrenal mass. Neither its function nor its embryology is related to the neighboring cortex. Instead, this portion of the adrenal gland, which lies at the center of the gland, is an integral part of the autonomic nervous system. Chromaffin cells of the medulla are innervated by preganglionic sympathetic fibers of T11 through L2,

making them analogous to cells of the sympathetic ganglia. The medulla secretes epinephrine (80%), norepinephrine (19%), and dopamine (1%). These substances, collectively known as *catecholamines*, are produced from the amino acid tyrosine and modulate the systemic stress response (Fig. 65-4) (Robertson, 1990; de Diego et al, 2008). The effects of these catecholamines are mediated through their binding to adrenoreceptors located on target organs. The nature of these effects depends on the adrenoreceptor types or subtypes located and stimulated on a particular end organ (Table 65-3) (Robertson, 1990; Guimaraes and Moura, 2001). It is interesting to note that the enzyme phenylethanolamine-N-methyltransferase (PNMT), which catalyzes the conversion of norepinephrine to epinephrine, is relatively unique to the adrenal medulla (the brain and organ of Zuckerkandl also express this enzyme). The function of this enzyme is potentiated by the presence of glucocorticoids, thereby creating one of the few physiologic links between the adrenal cortex and the medulla. **Localization of PNMT to the adrenal medulla explains why the gland is the primary source of systemic epinephrine**, despite the presence of similar chromaffin cells elsewhere in the sympathetic nervous system (Robertson, 1990). Similar to the physiology that controls norepinephrine release at synaptic nerve terminals, the storage and release of adrenal catecholamines involves intracellular vesicles. Liberation of these vesicles through exocytosis results in release of adrenal catecholamines into the bloodstream (Eisenhofer et al, 2004b).

The metabolism of catecholamines is complex, and some controversy still exists about the physiologic relevance of each pathway (Eisenhofer et al, 2004b). The majority of adrenal catecholamine metabolism occurs at the scene of production in cells of the adrenal medulla themselves (Eisenhofer et al, 2003a). For clinical purposes, three metabolites (metanephrine, normetanephrine, and vanillylmandelic acid [VMA]) and two enzymes (catechol-O-methyltransferase [COMT] and monoamine oxidase [MAO]) are important. Metanephrine and normetanephrine result from respective methylation of epinephrine and norepinephrine by COMT. Although large amounts of this enzyme are present in the liver and kidneys, the majority of adrenal catecholamine metabolites are methylated by COMT within the cells of the adrenal medulla (Eisenhofer et al, 2003a). Indeed, over 90% of metanephrine (epinephrine metabolite) and some 20% or more of normetanephrine (a norepinephrine metabolite) in the bloodstream are derived from the adrenal medulla. Therefore a measurable rise in the level of these metabolites is very useful when diagnosing potential pheochromocytomas (see section on *assessment of function of adrenal masses*) (Eisenhofer et al, 1995). In the urine, most of these metabolites are excreted in a sulfonated form. Furthermore, MAO and other enzymes subsequently participate in the conversion of catecholamine metabolites to VMA, the primary catecholamine metabolic end product that is largely formed by the liver. Nonadrenal catecholamines from the sympathetic nervous system are similarly converted to VMA (Eisenhofer et al, 2004b). Figure 65-4 summarizes the most clinically relevant aspects of the catecholamine metabolism pathway.

ADRENAL DISORDERS

Disorders of Increased Adrenal Function

Cushing Syndrome

Overview and Epidemiology. Hypercortisolism secondary to excessive production of glucocorticoids by the adrenal cortex is defined as Cushing syndrome (Orth and Liddle, 1971). The disease is rare and occurs in 2 to 5 of every million people per year (Lindholm et al, 2001; Findling and Raff, 2005). Diagnosis and treatment of Cushing syndrome is multifaceted, often requiring cooperation of internists, endocrinologists, neurosurgeons, and adrenal surgical experts (Newell-Price et al, 2006). The urologist must understand the comprehensive pathophysiology of hypercortisolism and have particularly advanced expertise in the aspects of this complex disease for which adrenalectomy is required.

Figure 65-4. Summary of catecholamine metabolism. The figure simplifies the metabolic pathway of norepinephrine and epinephrine degradation to highlight those metabolic products that play a role in routine clinical practice. Note: The central role that the monoamine oxidase (MAO) enzyme plays in catecholamine degradation is not fully reflected in this figure, because most metabolites that are produced by MAO catalysis are not routinely measured in laboratory assessments for pheochromocytoma. Key enzymes involved in catalysis of metabolic conversions are indicated in *italic font*. COMT, catechol-*O*-methyltransferase; PNMT, phenylethanolamine-*N*-methyltransferase.

KEY POINTS: PHYSIOLOGY

- Adrenal cortex and the adrenal medulla are best conceptualized as two distinct organs, the former endocrine and the latter neurocrine.
- Three main zones of the adrenal cortex are the zona glomerulosa, zona fasciculata, and zona reticularis, with each zone primarily responsible for mineralocorticoid, glucocorticoid, and androgen synthesis, respectively.
- Ratios and types of enzymes in each zone of the adrenal cortex vary, resulting in different hormonal products for each region.
- Aldosterone levels are primarily regulated by angiotensin II through the RAAS and directly by serum potassium levels. ACTH is less important in regulation of this region's function; therefore the zona glomerulosa is the only region of the adrenal cortex that does not atrophy on pituitary failure.
- Cortisol is the primary glucocorticoid in humans, and its secretion is under tight ACTH control.
- Pharmacologic manipulation of adrenal androgen production is an increasingly targeted strategy for treatment of advanced prostate cancer.
- Substances collectively known as *catecholamines*—epinephrine, norepinephrine, and dopamine—are produced from the amino acid tyrosine and modulate the systemic stress response.

Pathophysiology. The zona fasciculata of the adrenal cortex secretes more than 20 mg of cortisol every day (Arlt and Stewart, 2005). Regulation of this secretion is controlled through the hypothalamic-pituitary-adrenal (HPA) axis (Jacobson, 2005). A fluent understanding of this classic neuroendocrine negative feedback system is critical for the successful management of every Cushing patient.

Normal Hypothalamic-Pituitary-Adrenal Axis Physiology. Corticotrophic cells of the anterior pituitary secrete ACTH, also known as *corticotropin*, under the influence of neuronal innervations from the hypothalamus. Synthesis of ACTH is a result of cleavage of the pro-opiomelanocortin (POMC) precursor molecule. Physiologically, the most important promoter of ACTH release is corticotropin-releasing hormone (CRH), but oxytocin and vasopressin also play a role (Jacobson, 2005; Sam and Frohman, 2008). Stress, whether physiologic or psychologic, appears to be the most important variable in modulating activity of the HPA axis (Jacobson, 2005).

ACTH not only is responsible for promoting production of glucocorticoids and androgens by the adrenal cortex, but it also plays a critical role in maintaining adrenal cortical vitality. Indeed, without ACTH (e.g., when its secretion is suppressed by exogenous steroid intake), all but the mineralocorticoid-producing cells of the adrenal cortex arrest hormone production and undergo apoptosis (Arlt and Stewart, 2005; Jacobson, 2005). In addition to ACTH, splanchnic nerves that innervate the adrenals also appear to affect glucocorticoid production (Jacobson, 2005).

TABLE 65-3 Primary Effects of Catecholamines

EFFECTOR ORGANS	RECEPTOR TYPE	RESPONSES	MOST RELEVANT CLINICAL MANIFESTATIONS
Eye

Figure 65-5. The hypothalamic-pituitary-adrenal axis and feedback loop. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Glucocorticoids bind receptors in the hypothalamus and the pituitary and complete the negative feedback loop by inhibiting production of CRH and ACTH by these structures, respectively (Jacobson, 2005). Figure 65-5 summarizes the salient features of the HPA axis.

It is important to understand that CRH secretion is under tight control of the hypothalamic suprachiasmatic nucleus and follows circadian patterns. The highest level of cortisol in healthy subjects is detected in the mornings, and the nadir is observed at approximately 11 PM. Even small perturbations of this physiologic rhythm are considered pathologic (Jacobson, 2005; Sam and Frohman, 2008).

Overview of Cushing Syndrome. Given the sophistication of the HPA axis, hypercortisolism can result from a number of different pathologies that result in oversecretion of cortisol by the adrenal glands. Causes of Cushing syndrome can be divided into three main groups: (1) exogenous, (2) ACTH dependent, and (3) ACTH independent (Fig. 65-6). Exogenous Cushing syndrome is a result of iatrogenic glucocorticoid administration. ACTH-dependent disease results from an elevated serum corticotropin level caused by pathology extrinsic to the adrenal gland and accounts for up to 85% of cases of endogenous Cushing syndrome. ACTH-independent hypercortisolism, on the other hand, results from unregulated overproduction of glucocorticoids by the adrenal(s) and is relatively rare. The adrenal surgeon has long been involved in management of ACTH-independent disease, but with the advent of laparoscopy, adrenal surgery for ACTH-dependent Cushing syndrome is becoming more commonplace (Porterfield et al, 2008).

Exogenous Cushing Syndrome. Exogenous Cushing syndrome is the most common cause of hypercortisolism in patients of the Western world (Newell-Price et al, 2006). Synthetic glucocorticoids are frequently used in treatment of many conditions, and Cushing syndrome can result from the administration of even low doses of exogenous steroids orally, topically, or by inhaled preparations (Hopkins and Leinung, 2005; Newell-Price et al, 2006). A careful patient history is therefore essential in the evaluation of all patients with Cushing syndrome. The clinician also must be cognizant of the possibility that the patient either is unaware of his or her steroid use (e.g., use of herbal remedies, nasal sprays) or is surreptitiously self-administering glucocorticoids (e.g., for performance enhancement) (Hopkins and Leinung, 2005).

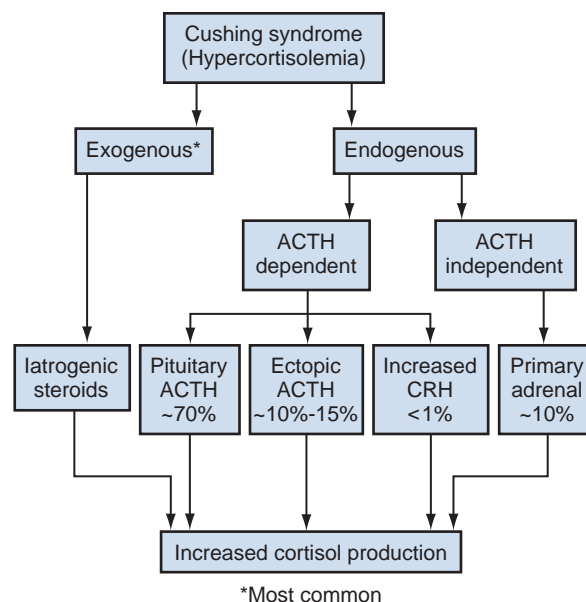

Figure 65-6. Clinically relevant causes of excess cortisol production. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Adrenocorticotropic Hormone–Dependent Cushing Syndrome

Overview. ACTH-dependent hypercortisolism accounts for 80% to 85% of endogenous Cushing syndrome. Approximately 80% of ACTH-dependent disease results from primary pituitary pathology and is known as *Cushing disease*. Ectopic ACTH production is the other main cause of ACTH-dependent hypercortisolism (Newell-Price et al, 2006). Ectopic CRH syndrome is a third cause of ACTH-dependent Cushing syndrome and is extremely uncommon (see Fig. 65-6) (Orth, 1995).

Cushing Disease. Described by the neurosurgical pioneer Harvey Cushing in 1932, Cushing disease causes hypercortisolism through excessive secretion of ACTH by the pituitary gland (Cushing, 1932). The condition accounts for nearly 70% of endogenous Cushing syndrome. The most common culprit is a corticotropin-producing microadenoma. Large macroadenomas 1 cm or greater are found in only about 5% of cases (Newell-Price et al, 2006). Fifteen percent of functional pituitary adenomas exhibit the ability to secrete ACTH (Shimon and Melmed, 1998). Hyperplasia of ACTH-producing cells and pituitary carcinoma can also oversecrete ACTH but are extremely rare (Orth, 1995). Up to two thirds of individuals with Cushing disease are female (Scott and Orth, 1990).

Ectopic Adrenocorticotropic Hormone Syndrome. Production of ACTH by nonpituitary tumors can also result in hypercortisolism. These corticotropin-producing tissues are nearly always malignant and account for approximately 10% of Cushing syndrome (Porterfield et al, 2008). Liddle and associates first described the phenomenon in the early 1960s and termed it *ectopic ACTH syndrome* (Meador et al, 1962; Scott and Orth, 1990). The timing and onset of hypercortisolism varies and can precede the diagnosis of an extra-adrenal malignancy by many years, resulting in diagnostic difficulties and the clinical conundrum wherein a subclinical pituitary adenoma is suspected but not radiographically identified (Aniszewski et al, 2001). Moreover, hypercortisolism in end-stage debilitated cancer patients is almost certainly underdiagnosed (Orth, 1995). As a result of higher ACTH levels, the adrenal glands of patients with ectopic ACTH syndrome are usually more markedly hyperplastic and thereby larger than those of patients with Cushing disease (Jenkins et al, 1999). Table 65-4 summarizes primary malignancies implicated in ectopic ACTH production, which notably includes pheochromocytoma.

Modified from Aniszewski JP, Young WF Jr, Thompson GB, et al. Cushing syndrome due to ectopic adrenocorticotrophic hormone secretion. *World J Surg* 2001;25(7):934–40.

Ectopic Corticotropin-Releasing Hormone. Production of CRH by malignancies is extremely rare and is responsible for less than 1% of cases of Cushing syndrome. Bronchial carcinoma is the most common culprit, and concurrent ACTH secretion is not unusual (Carey et al, 1984; Orth, 1995).

Adrenocorticotrophic Hormone-Independent Cushing Syndrome. Uncontrolled hypersecretion of cortisol by adrenal tissues accounts for a minority of endogenous hypercortisolism and is classified as ACTH-independent Cushing syndrome. Adrenal neoplasms and rare forms of bilateral adrenal disease are responsible for this group of conditions (Lacroix and Bourdeau, 2005; Newell-Price et al, 2006).

Adrenal Tumors. Cortisol-secreting benign adenomas of the adrenal gland are responsible for approximately 10% of Cushing syndrome and often result from a dominant unilateral hyperplastic nodule, although multifocal bilateral functional adrenal hyperplasia may also occur. Less than 10% of adrenal masses are bilateral and often present a diagnostic challenge (Lacroix and Bourdeau, 2005; Porterfield et al, 2008; Young et al, 2008). Radiographically undetectable benign adrenal cortisol-producing lesions may also be responsible for cases of subclinical Cushing syndrome (Rossi et al, 2000). Cortisol production by adrenocortical carcinomas (ACCs) accounts for approximately 8% of patients with Cushing syndrome and appears to be an independent predictor of poor outcome for patients with ACC (Lindsay and Nieman, 2005a; Berruti et al, 2014). Cushingoid phenotype resolves for most patients within 7 to 9 months after adrenalectomy; however, it can persist for several years in some individuals (Sippel et al, 2008).

Adrenocorticotrophic Hormone-Independent Macronodular Adrenal Hyperplasia. ACTH-independent bilateral macronodular adrenal hyperplasia (AIMAH) gives rise to less than 1% of Cushing syndrome. The condition is characterized by multiple large (up to 4 cm) nodules replacing the glands, with each adrenal weighing over 60 g (Lacroix and Bourdeau, 2005; Iacobone et al, 2008).

Weights in excess of 200 g have been reported for each gland affected by AIMAH (Swain et al, 1998). It is essential that this disease entity be distinguished from adrenal enlargement caused by chronic adrenal stimulation in ACTH-dependent Cushing syndrome; radiographic images of the adrenals appear similar in both conditions. Bilateral macronodular hyperplasia is observed as a feature of the McCune-Albright syndrome, which also includes polyostotic fibrous dysplasia, dermatologic manifestations, and other endocrine abnormalities (Lacroix and Bourdeau, 2005).

Primary Pigmented Nodular Adrenocortical Disease. Like AIMAH, primary pigmented nodular adrenocortical disease (PPNAD) is exceedingly rare, accounting for less than 1% of cases of Cushing syndrome. Unlike AIMAH, however, the adrenal glands in this condition remain normal in size and exhibit black or brown cortical nodules (Young et al, 1989). The cortical tissue surrounding the nodules is atrophic, and the adrenal medulla is free of disease (Lacroix and Bourdeau, 2005). Approximately half of PPNAD is found in patients with the autosomal dominant Carney complex, which is also responsible for spotty skin and mucous membrane lesions, and a variety of neoplasms that include Sertoli cell tumors. The other half of cases of PPNAD are nonhereditary with no known cause (Lacroix and Bourdeau, 2005).

Clinical Characteristics

Classical Cushing Syndrome. Clinical characteristics of Cushing syndrome vary considerably among affected patients. Many of the classic symptoms of hypercortisolism, such as central obesity, moon facies, buffalo hump, proximal muscle weakness, easy bruisability, and abdominal striae, are nonspecific. It is the combination of these and other clinical signs that should raise suspicion and prompt potential screening for Cushing syndrome (Findling and Raff, 2005). Cushing syndrome also results in systemic symptomatology, such as central obesity, dyslipidemia, insulin resistance, and hypertension, that is identical to the highly-prevalent metabolic syndrome (Pivonello et al, 2005,

Figure 65-7. Diverse effects of hypercortisolism on organ systems.

2008). Figure 65-7 depicts the effects of glucocorticoids on organ systems, and Table 65-5 summarizes signs and symptoms of the disease and indicates their frequency. Screening for Cushing syndrome is usually beyond the scope of urologic practice; however, it is important for urologists to appreciate the **relatively common occurrence of hypogonadal hypogonadism in men with Cushing syndrome**. A low threshold for initiating a hypercortisolism workup should exist for these men with libido or erectile problems, low testosterone, and low gonadotropin levels (Findling and Raff, 2005; Pivonello et al, 2008). **Up to 50% of patients with Cushing syndrome exhibit urolithiasis**; therefore stone formers with cushingoid features also should receive a hypercortisolemia evaluation. It is interesting to note that definitive treatment of Cushing syndrome in these patients reduces the risk of stone formation but does not bring the risk back to that of the general population (Faggiano et al, 2003).

Subclinical Cushing Syndrome. Subclinical Cushing syndrome is a relatively new disease entity consisting of hypercortisolemia in the absence of an overt cushingoid phenotype. Obvious clinical signs of Cushing syndrome are absent, and the diagnosis is made when a metabolic workup for an incidentally discovered adrenal mass reveals hypercortisolemia (Sippel and Chen, 2004). In the past, the disease entity was referred to as *pre-Cushing syndrome*, *noncushingoid Cushing syndrome*, and *preclinical Cushing syndrome*; however, the term *subclinical Cushing syndrome* has gained acceptance. The term *subclinical autonomous glucocorticoid hypersecretion* also has been introduced (Tsagarakis et al, 2006). Classically, the disease entity applies to patients who are found to have elevated cortisol levels

on a metabolic workup of an adrenal incidentaloma. **Nearly 10% of patients in one large series of adrenal incidentalomas were found to have the condition** (Mantero et al, 2000). Patients can also fall under the umbrella of this diagnosis when Cushing syndrome is discovered during screening. For instance, when patients with type 2 diabetes and poor glucose control are screened for hypercortisolism, some 2% have subclinical Cushing syndrome (Catargi et al, 2003).

Adrenalectomy in the setting of subclinical Cushing syndrome may improve glucose control and hypertension and result in weight loss (Midorikawa et al, 2001; Mitchell et al, 2007). Surgical indications and benefits for subclinical Cushing syndrome, however, are still a matter of debate (Sippel and Chen, 2004; Tsagarakis et al, 2006). Some authors argue that adrenalectomy should be performed only in patients who are potentially symptomatic and exhibit clinical signs, such as hypertension, obesity, glucose intolerance, or osteopenia. Others propose that surgery must be offered to all patients to prevent the sequelae of hypercortisolism (Sippel and Chen, 2004; Pivonello et al, 2005; Tsagarakis et al, 2006). Patients with subclinical Cushing syndrome may be at higher risk for postadrenalectomy adrenal insufficiency than patients with non-cortisol-secreting adrenal pathologies, because functionality of the contralateral gland may be suppressed (Tsagarakis et al, 2006).

Diagnostic Tests. The diagnosis of Cushing syndrome is one of the most complex and difficult tasks in clinical endocrinology and most often falls outside of the realm of medical or surgical urologic practice (Findling and Raff, 2005). Nevertheless, the urologist must be familiar with these diagnostic strategies and how they relate to

TABLE 65-5 Signs and Symptoms of Cushing Syndrome

SYMPTOMS AND SIGNS	PREVALENCE (%)
Central obesity	90-100

the etiology of hypercortisolism. Moreover, the urologist who offers adrenalectomy must be well versed in the basic metabolic evaluation for Cushing syndrome in patients with adrenal masses.

Establishing the Diagnosis of Cushing Syndrome. When the diagnosis of Cushing syndrome is suspected, the clinician can choose among several laboratory studies. The two evaluations performed most frequently are the 24-hour urinary free cortisol (UFC) evaluation and the overnight low-dose dexamethasone suppression test (LD-DST). The sensitivity of the former test, however, may not be adequate for screening patients with incidentalomas (Nieman et al, 2008). Late-night salivary cortisol is a test that is becoming increasingly popular. Second-line tests include the 2-day LD-DST and midnight plasma cortisol testing (Arnaldi et al, 2003; Newell-Price et al, 2006; Nieman et al, 2008; Pivonello et al, 2008). The physiologic principles underlying these tests are important to understand and are described in this section (Findling and Raff, 2005). The section on evaluation of adrenal pathology in urologic practice outlines practical algorithms for the metabolic evaluation of adrenal lesions. Tests such as random serum cortisol, plasma ACTH level, urinary 17-ketosteroid level, insulin tolerance testing, and loperamide testing have fallen out of favor and are no longer recommended (Nieman et al, 2008).

Administration of low-dose dexamethasone followed by measurement of serum cortisol the next morning probes the patient's glucocorticoid negative feedback system. In subjects without hypercortisolism, dexamethasone acts on the corticotrophic cells of the anterior pituitary, suppresses ACTH production, and thereby results in a reduction of serum cortisol levels (Findling and Raff, 2005). A key element to understanding this test is that despite the “low-dose” designation, the dose of dexamethasone administered for this study corresponds to threefold to fourfold levels of physiologic glucocorticoid. It is important to note that the exogenous dexamethasone is not detected by the serum cortisol assay. The fact that patients with ACTH-independent Cushing syndrome and those

with ectopic ACTH secretion fail to suppress cortisol production during such testing is intuitive; however, the reason for the failure of patients with ACTH-producing pituitary adenomas (Cushing disease) to suppress cortisol secretion after low-dose dexamethasone administration is less obvious. The phenomenon is best understood by the relative insensitivity of pituitary adenomas to the inhibitory effects of glucocorticoid stimulation (Raff and Findling, 2003). In summary, a patient's failure to suppress cortisol levels after an overnight low-dose dexamethasone administration is indicative of Cushing syndrome. **This test does not delineate the cause of hypercortisolism, but simply suggests its presence.** Administration of low-dose dexamethasone over a 48-hour period is less practical and is reserved for second-line testing.

The UFC evaluation is a 24-hour direct measurement of free bioavailable cortisol. Unlike serum cortisol testing, which measures both free and bound cortisol, urinary cortisol measurements are independent from the variables that influence corticosteroid-binding globulin levels (Arnaldi et al, 2003). Moreover, the test is an integrated measurement of cortisol secretion over a 24-hour period. This feature of the study is critical, because serum cortisol levels exhibit some circadian variation even in many patients with Cushing syndrome (Orth, 1995). **The urologist must be cognizant that this test may not possess sufficient sensitivity for diagnosis of subclinical Cushing syndrome, and the Endocrine Society recommends against it for metabolic evaluation of adrenal incidentalomas (Nieman et al, 2008).**

Late-night salivary cortisol and midnight plasma cortisol measurements take advantage of a common feature of all causes of Cushing syndrome—a perturbation and in some cases complete disruption in the diurnal variation of cortisol levels. The abnormality, even in very mild cases of Cushing syndrome, is the inability to suppress cortisol levels at night. As previously mentioned, peak morning cortisol levels in patients with Cushing syndrome are often within the normal range; however, persistent elevation at night may signal the loss of diurnal variance associated with Cushing syndrome. Although midnight plasma cortisol measurements are clinically impractical in an outpatient setting, late-night salivary cortisol measurements are becoming a popular diagnostic tool for identification of hypercortisolism (Raff and Findling, 2003; Findling and Raff, 2005).

It is important to note that other conditions can stimulate the HPA axis and emulate Cushing syndrome (Box 65-1); therefore endocrinologic expertise is recommended when definitively diagnosing hypercortisolism (Nieman et al, 2008).

Identifying the Cause of Cushing Syndrome. Once Cushing syndrome has been diagnosed, its cause must be localized. Because of the nuanced complexity of this process, some authors believe that this is best done by endocrinologists at major referral centers (Newell-Price et al, 2006). Briefly, the algorithm is as follows.

First, ACTH-dependent disease must be distinguished from the ACTH-independent causes. This is done by measurement of serum ACTH. Low serum ACTH points to ACTH-independent pathology, and abdominal imaging is indicated to identify the adrenal source. If the adrenals are unremarkable on cross-sectional imaging, exogenous steroids as a cause of Cushing syndrome, or much less commonly PPAD, must be suspected (Arnaldi et al, 2003). It is interesting to note that the presence of PPAD often can be confirmed by a delayed “paradoxical rise” in the 24-hour urinary cortisol sampling after dexamethasone administration (Lacroix and Bourdeau, 2005). Up to 10% of patients with adrenal Cushing syndrome have bilateral adrenal lesions (Lacroix, 2008). Adrenal venous sampling may be helpful in this setting (Young et al, 2008).

The true diagnostic difficulty lies in distinguishing Cushing disease from the ectopic ACTH syndrome for patients who have high serum ACTH levels. This problem stems from the fact that both pituitary microadenomas and ACTH-producing tumors can be very difficult to localize with modern imaging. Meanwhile, incidental imaging findings in the lungs, pancreas, and pituitary are relatively common, often clouding the diagnostic waters (Newell-Price et al, 2006). For instance, 10% of the general population exhibit an abnormality on imaging of the pituitary gland, whereas some 50%

Figure 65-8. Bilateral adrenal enlargement in a patient with advanced metastatic adenocarcinoma of the pancreas.

BOX 65-1 Causes of Hypercortisolism in the Absence of Cushing Syndrome

Some clinical features of Cushing syndrome may be present:

- Pregnancy
- Depression
- Alcohol dependence
- Glucocorticoid resistance
- Morbid obesity
- Poorly controlled diabetes mellitus

Unlikely to have any clinical features of Cushing syndrome:

- Physical stress (hospitalization, surgery, pain)
- Malnutrition, anorexia nervosa
- Intense chronic exercise
- Hypothalamic amenorrhea
- Corticosteroid-binding globulin excess (increased serum but not in urine cortisol)

Although Cushing syndrome is unlikely in these conditions, it may rarely be present. If there is a high clinical index of suspicion, the patient should undergo testing, particularly those within the first group.

Modified from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab* 2008;93(5):1526–40.

of patients with Cushing disease have no abnormality on pituitary MRI (Fig. 65-8) (Arnaldi et al, 2003; Porterfield et al, 2008).

Direct measurements of ACTH in a downstream venous plexus that drains the pituitary—the inferior petrosal sinus—after CRH stimulation has become the gold standard approach for distinguishing ectopic ACTH production from Cushing disease. High levels of ACTH in the inferior petrosal sinus, when compared with those in peripheral blood, indicate Cushing disease, whereas levels similar to peripheral plasma suggest an ectopic ACTH source (Findling and Raff, 2006; Porterfield et al, 2008).

High-dose dexamethasone suppression testing was used in the past to differentiate pituitary and ectopic ACTH sources, but the value of the test is limited. The study is based on the principle that high enough doses of dexamethasone should suppress ACTH production by pituitary adenomas, whereas ectopic ACTH

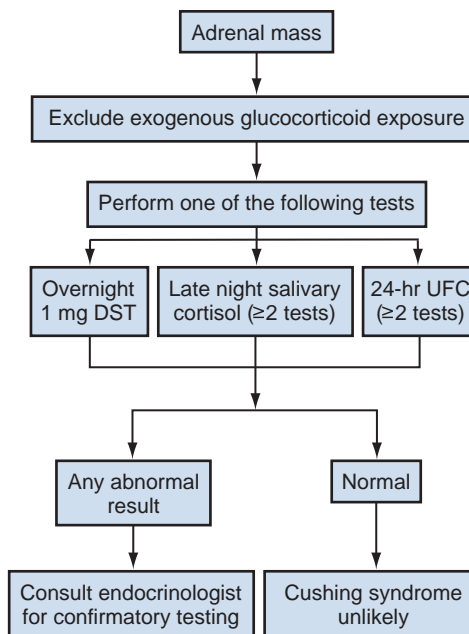

Figure 65-9. Testing algorithm for ruling out hypercortisolemia secondary to an adrenal mass. In case of a positive result during late-night salivary cortisol or 24-hour urinary free cortisol evaluations, repeat testing is often prudent. DST, dexamethasone suppression test; UFC, urinary free cortisol.

production continues despite the high-dose glucocorticoid administration (Arnaldi et al, 2003). Unfortunately, it is now clear that some nonpituitary ACTH-producing tumors possess the glucocorticoid receptor and also reduce ACTH production on high-dose dexamethasone administration (Aron et al, 1997; Raff and Findling, 2003). Currently, high-dexamethasone suppression testing is not routinely used (Fig. 65-9) (Findling and Raff, 2006; Porterfield et al, 2008).

Treatment. The treatment of Cushing syndrome must be approached as a multidisciplinary endeavor. Primary care physicians, endocrinologists, neurosurgeons, and the adrenal surgical experts must effectively communicate not only with the patient but also with one another. Treatment goals involve correction of hypercortisolemia, restoration of the HPA axis, and management of Cushing syndrome sequelae (Porterfield et al, 2008).

Exogenous Cushing Syndrome. Correction of exogenous Cushing syndrome, when appropriate, must be handled with proper care. Cessation of glucocorticoid administration must be gradual, so that the HPA axis has ample time to recover. The process can take weeks to months and varies greatly from patient to patient. The physician must be aware of the clinical entity known as *steroid withdrawal syndrome*, wherein the patient cannot tolerate steroid dose reduction despite apparent normalization in HPA axis testing (Hopkins and Leinung, 2005).

Adrenocorticotrophic Hormone-Dependent Disease

Cushing Disease. The current standard of care for ACTH-secreting pituitary adenomas is trans-sphenoidal surgical resection (see Fig. 65-10 on the Expert Consult website). Unfortunately, cure is seen in only 60% to 80% of patients (Newell-Price et al, 2006; Pivonello et al, 2008). Furthermore, long-term follow-up is necessary, because up to 25% of individuals relapse (Patil et al, 2008). In addition, macroadenomas are resistant to neurosurgical treatment, and less than 15% of patients are cured after excision of tumors 1 cm or larger (Newell-Price et al, 2006). After resection, a severe Addisonian state is common, and careful glucocorticoid replacement is necessary in the year after surgery (Utz et al, 2005). Hypopituitarism after resection of a pituitary adenoma is a known complication, with rates varying from less than 5% to more than 50% for the various pituitary metabolic products in various surgical series. Careful patient monitoring by expert endocrinologists is

essential (Utz et al, 2005; Porterfield et al, 2008). Neurosurgical reoperation after initial failure is challenging, and success rates vary. Moreover, the risk of hypopituitarism also significantly rises with secondary resections (Utz et al, 2005; Porterfield et al, 2008). Salvage radiation therapy is an option, but the patient must be warned about significant delays in reduction of ACTH secretion and the possibility of hypopituitarism (Estrada et al, 1997; Utz et al, 2005; Porterfield et al, 2008).

The urologist must be involved when adrenalectomy is contemplated or required. Currently, bilateral adrenalectomy is most often recommended when at least one attempt to treat the primary tumor has failed. It is also necessary in rare instances when hypercortisolism is life-threatening and swift definitive treatment is mandatory. The advantages of the procedure include a lack of postoperative hypopituitarism and an extremely high success rate with rapid resolution of hypercortisolism (Vella et al, 2001; Chow et al, 2008; Lacroix, 2008). Nevertheless, lifelong mineralocorticoid and glucocorticoid replacement is required in all patients. Moreover, the patients are at risk for progressive growth of their pituitary adenoma, mainly resulting in complications such as ocular chiasm compression, oculomotor deficiencies, and, rarely, a rise in intracranial pressure (Assie et al, 2007). This results in the Nelson-Salassa syndrome (also known as Nelson syndrome), which is found in 8% to 29% of patients who have undergone bilateral adrenalectomy in large series. Prophylactic radiation therapy has been shown to prevent the phenomenon in some but not all published reports (Gil-Cárdenas et al, 2007). Currently, routine use of prophylactic radiotherapy to prevent Nelson syndrome after bilateral adrenalectomy is controversial (Porterfield et al, 2008). When counseling patients regarding bilateral adrenalectomy for ACTH-dependent Cushing syndrome, the urologist must also warn of the rare possibility of residual, functioning adrenal tissue remaining after the procedure (Kemink et al, 1992).

Ectopic Adrenocorticotrophic Hormone Syndrome. Resection of the primary ACTH-producing tumor is the single best therapeutic approach to normalizing cortisol levels in patients with ectopic ACTH syndrome. In large series, however, primary tumor resection is possible in only approximately 10% of patients (Aniszewski et al, 2001). For patients with unresectable primary tumors or whose primary ACTH-producing tissue cannot be identified (up to 35% of patients), bilateral adrenalectomy with lifelong replacement therapy is an excellent therapeutic option (Aniszewski et al, 2001; Porterfield et al, 2008).

Adrenocorticotrophic Hormone-Independent Disease. Patients with unilateral cortisol-secreting adrenal masses are treated with ipsilateral adrenalectomy. Partial adrenalectomy is possible when preservation of adrenal tissue is deemed essential (Walz, 2004). Case reports of bilateral partial adrenalectomies for cortisol-producing masses exist in the literature (Inoue et al, 2006). The current standard of care for AIMAH and PPNAD patients is bilateral adrenalectomy with lifelong replacement therapy. Success with unilateral resection of the largest gland in AIMAH patients also has been reported (Iacobone et al, 2008).

Medical Treatment of Hypercortisolism. Medical therapy for hypercortisolism is used for bridging a patient to surgery or when surgical intervention is not possible. Medications that block enzymes of steroid synthesis, such as metyrapone, aminoglutethimide, trilostane, ketoconazole, and etomidate, are often used. Mitotane, a medication that is discussed in further detail in the section on adrenal carcinomas, can also be used (Porterfield et al, 2008). In the future, inhibitors of 17 α -hydroxylase (CYP17), such as abiraterone, may also be of some use; however, at this point such use of these drugs remains largely unexplored (Attard et al, 2009). Medical treatment of hypercortisolemia requires significant expertise and should be left to expert endocrinologists.

Prognosis. Life expectancy for patients with Cushing syndrome falls short of that of patients with normal cortisol levels. Normalization of hypercortisolemia may reduce but not eradicate this risk (Swearingen et al, 1999; Pivonello et al, 2005). Aggressive management of cardiovascular risk factors under the watchful eyes of

experienced medical experts is paramount even in patients whose laboratory values return to normal after successful treatment.

Summary. Cushing syndrome is a complex disorder that requires a multidisciplinary approach. The urologist plays a critical role in management of the hypercortisolemic patient when unilateral or bilateral adrenalectomy is required. A thorough understanding of relevant pathophysiology is necessary not only for diagnosis and treatment, but also for appropriate perioperative counseling of patients with Cushing syndrome.

KEY POINTS: CUSHING SYNDROME

- Serum cortisol levels are under tight control. In healthy subjects, peaks occur in the morning and the nadir is observed at approximately 11:00 PM.
- Adrenal tumors that secrete cortisol cause ACTH-independent Cushing syndrome and account for approximately 10% of Cushing syndrome that is not caused by steroid intake.
- Patients with undiagnosed Cushing syndrome can have hypogonadal hypogonadism or urolithiasis on presentation to the urologist.
- Testing of adrenal masses for cortisol hypersecretion is mandatory.

Primary Aldosteronism

Overview and Epidemiology. Dr. Jerome Conn first described primary aldosteronism in 1955 in a 34-year-old woman with hypertension and hypokalemia (Conn, 1955). Urine assays demonstrated a markedly elevated level of mineralocorticoid activity. The patient's condition greatly improved after the removal of a 4-cm unilateral adrenal tumor. Since this initial case report, several subtypes of primary aldosteronism, which require distinct evaluation and treatment, have been identified. Primary aldosteronism is the most common form of secondary hypertension, with a prevalence ranging from 5% to 15% of hypertensive patients in contemporary series; thus it is important for urologists to be familiar with appropriate diagnostic and management strategies (Mulatero et al, 2004; Rossi et al, 2006a; Young, 2007a; Jansen et al, 2014).

Pathophysiology. The RAAS is a key regulator of blood pressure and extracellular fluid volume (Fig. 65-11). The release of renin from the juxtaglomerular cells is the rate-limiting step in the RAAS cascade. Under normal physiologic conditions, renin release is stimulated by low renal perfusion pressure, increased renal sympathetic nervous activity, and low sodium concentration sensed by the macula densa (Gibbons et al, 1984). Renin then cleaves angiotensinogen to angiotensin I, which in turn is cleaved by angiotensin-converting enzyme (ACE) to angiotensin II. Angiotensin II both functions as a potent vasoconstrictor and triggers the release of aldosterone from the zona glomerulosa. Additional regulators of aldosterone release include potassium and ACTH. In primary aldosteronism, aldosterone secretion is independent of the RAAS, and plasma renin levels will be suppressed. This finding is in contrast to patients with secondary hyperaldosteronism, in whom elevated renin levels are the cause of elevations in aldosterone secretion. This distinction between plasma renin levels in primary and secondary hyperaldosteronism is a critical concept used when screening for primary aldosteronism (see diagnosis section, later).

After release from the adrenal cortex, aldosterone increases sodium reabsorption and potassium secretion in the distal nephron (Nyirenda and Padfield, 2007). Hyponatremia does not occur because sodium reabsorption is accompanied by water uptake, thereby maintaining isotonicity. The resultant volume expansion is limited by mineralocorticoid escape. Mineralocorticoid escape is mediated by pressure-natriuresis, atrial natriuretic peptide secretion, and changes in electrolyte transporters in the distal nephron,

which result in limiting volume expansion to approximately 1.5 kg or less (Burnett et al, 1985; Yokota et al, 1994; Knepper et al, 2003).

Although the finding of increased plasma aldosterone and decreased plasma renin activity (PRA) is common to all patients with primary aldosteronism, individual subtypes of the disorder have distinct underlying pathophysiology. Differentiation between subtypes of primary aldosteronism is essential to ensure proper treatment. The causes of primary aldosteronism are presented in Figure 65-12. Idiopathic hyperplasia and aldosterone-producing adenomas are by far the most common subtypes encountered, accounting for over 95% of cases. Although idiopathic hyperplasia is the most common subtype diagnosed, the prevalence of aldosterone-producing adenomas may be greater than previously thought owing to lack of routine lateralization studies in patients diagnosed with primary aldosteronism (Mulatero et al, 2004).

The underlying pathophysiology of idiopathic hyperplasia, also referred to as *bilateral adrenal hyperplasia*, remains unknown. Macronodular hyperplasia is rare, with most cases attributed to micronodular hyperplasia (Schirpenbach and Reincke, 2007). Clinically, patients with idiopathic hyperplasia have less severe hypertension and are less likely to be hypokalemic compared with patients with aldosterone-producing adenomas (Rossi et al, 2006a). Whereas

both adrenal glands are responsible for increased aldosterone production in idiopathic hyperplasia, unilaterally adrenalectomy is not therapeutic. Unilateral adrenal hyperplasia is distinctly uncommon, but when appropriately diagnosed is potentially curable with adrenalectomy after confirmation of lateralizing aldosterone secretion (see the section on *subtype differentiation*). In comparison with idiopathic hyperplasia, aldosterone-producing adenomas are associated with more profound hypertension and hypokalemia (Rossi et al, 2006a).

Less common causes of primary aldosteronism include ACCs, ectopic aldosterone-producing tumors, and familial hyperaldosteronism (FH). Primary aldosteronism associated with ACC is rare, representing less than 1% of cases of primary aldosteronism and 2.5% to 5% of ACCs (Ng and Libertino, 2003; Seccia et al, 2005). Ectopic aldosterone-producing tumors are extremely rare and should raise suspicion for the presence of accessory adrenal tissue or adrenal heterotopia (Abdelhamid et al, 1996).

Three types of FH have been described: type I, type II, and type III (Viola et al, 2013). FH type I, also known as glucocorticoid-remediable aldosteronism, is an autosomal dominant genetic disorder driven by the chimeric fusion of the promoter region of the 11 β -hydroxylase gene (*CYP11B1*) and the coding region of the aldosterone synthase gene (*CYP11B2*). This combination results in aldosterone synthase activity being controlled by ACTH. Thus aldosterone is secreted according to the circadian rhythm of ACTH instead of the RAAS (Lifton et al, 1992). Patients with FH type I will often have early-onset refractory hypertension and a family history of early onset hypertension or cerebral vascular accidents (Litchfield et al, 1998; McMahon and Dluhy, 2004). FH type II is a genetically heterogeneous disease with an autosomal dominant inheritance pattern. Affected families will demonstrate either idiopathic hyperplasia or aldosterone-producing adenomas that are clinically and morphologically indistinguishable from sporadic cases of primary aldosteronism. Linkage analysis suggests that mutations in the 7p22 region are responsible for FH type II in some families (Mulatero et al, 2004; So et al, 2005). FH type III is characterized by bilateral adrenal hyperplasia, refractory hypertension, severe hypokalemia, and the overproduction of hybrid steroids (Geller et al, 2008). Genetic mutations of *KCNJ*, which encodes for a potassium channel, have been identified as the cause of FH type III (Charmandari et al, 2012; Mulatero et al, 2012).

Clinical Characteristics. The diagnosis of primary aldosteronism is usually made during the third to sixth decades of life in patients being evaluated for refractory hypertension. The degree of hypertension is typically graded as moderate to severe, with a mean blood pressure of 184/112 noted in a retrospective series of 262 patients with primary aldosteronism (Young and Klee, 1988). In the prospective series by Rossi and colleagues (2006a), which evaluated the prevalence of primary aldosteronism in 1125 newly diagnosed hypertensive patients, the mean blood pressure (154/98) was significantly higher than in patients without primary aldosteronism

Figure 65-11. Renin-angiotensin-aldosterone system. Under normal conditions, aldosterone secretion is under the control of angiotensin II, serum potassium levels, and adrenocorticotropic hormone (ACTH). In primary aldosteronism, aldosterone is autonomously released, resulting in decreased plasma renin levels.

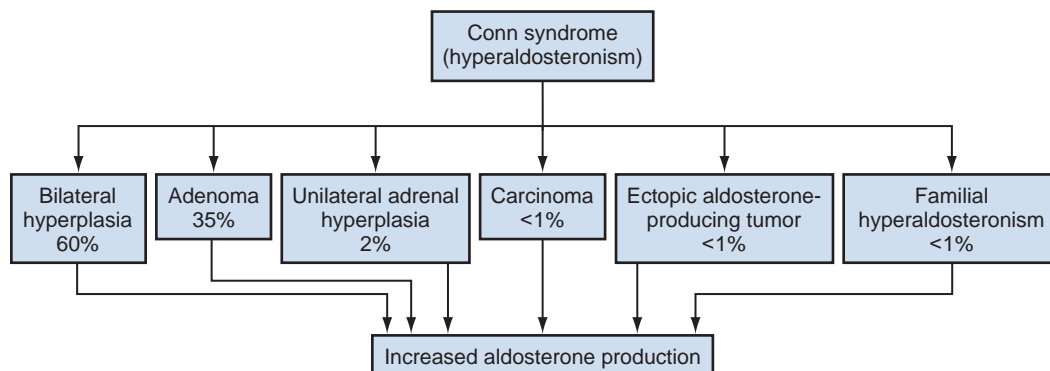

Figure 65-12. Subtypes of primary aldosteronism. (Modified from Young WF. Primary aldosteronism: renaissance of a syndrome. Clin Endocrinol [Oxf] 2007;66:607–18.)

(147/95) (Rossi et al, 2006a). The association between primary aldosteronism and the severity of hypertension has been demonstrated by Mosso and colleagues (2003), who noted a 2%, 8%, and 13% prevalence of primary aldosteronism in hypertensive patients stratified as stage 1 (140 to 159/90 to 99), stage 2 (160 to 179/100 to 109), and stage 3 ($>180/>110$) hypertension, respectively.

Although hypokalemia has been classically described as a common finding in primary aldosteronism, in contemporary series 63% to 91% of newly diagnosed patients are normokalemic at the time of diagnosis (Mulatero et al, 2004). In a minority of patients, hypokalemia is associated with symptoms including headaches, polydipsia, palpitations, polyuria, nocturia, and muscle weakness (Young, 2007a). Because of mineralocorticoid escape, hypernatremia is an uncommon finding in primary aldosteronism, with serum sodium levels similar to those in other forms of hypertension (Rossi et al, 2006a; Young, 2007a).

Cardiovascular and renal damage is a concern for all patients with hypertension and underlies the need for treatment. The incidence and severity of target organ damage appears to be increased in patients with primary aldosteronism compared with other forms of hypertension (Mulatero et al, 2013). Cardiac abnormalities, including left ventricular filling and diastolic dysfunction, increased left ventricular mass measurement, and prolonged QP interval have all been associated with primary aldosteronism (Rossi et al, 1996; Tanabe et al, 1997). These findings may help to explain the significant increase of cardiovascular events noted in patients with primary aldosteronism by Milliez and colleagues. In a retrospective series of patients with hypertension, patients with primary aldosteronism were 4 times more likely to be diagnosed with a stroke, 6.5 times more likely to be diagnosed with a myocardial infarction, and 12 times more likely to be diagnosed with atrial fibrillation compared with patients with essential hypertension (Milliez et al, 2005; Gonzaga and Calhoun, 2008). The increased risk of cardiovascular disease may be associated with the increased prevalence of metabolic syndrome that has been noted in this patient population (Fallo et al, 2006). Fortunately, appropriate treatment of primary aldosteronism has been associated with left ventricular remodeling, which may decrease the risk of future cardiac events (Rossi et al, 2014). In addition, patients with primary aldosteronism demonstrate increased rates of proteinuria and development of type 2 diabetes when compared with patients with essential hypertension (Fox et al, 2006; Rossi et al, 2006b; Mulatero et al, 2013).

Diagnostic Tests. The diagnosis of primary aldosteronism requires screening, confirmatory testing, and subtype differentiation. Indications for screening are listed in Box 65-2. The accurate diagnosis of primary aldosteronism and subtype differentiation is critical because of the associated increased risk of target organ damage, proper selection of antihypertensives, and potential for surgical cure in appropriately selected patients.

BOX 65-2 Indications for Primary Aldosterone Screening

- Hypertension with hypokalemia
- Resistant hypertension (three or more oral agents with poor control)
- Adrenal incidentaloma with hypertension
- Early-onset hypertension (<20 years) or stroke (<50 years)
- Severe hypertension ($\geq 160/\geq 110$)
- Whenever considering secondary causes of hypertension (i.e., pheochromocytoma or renovascular disease)
- Unexplained hypokalemia (spontaneous or diuretic induced)
- Evidence of target organ damage disproportionate to degree of hypertension
- Hypertension with family history of primary aldosteronism

Screening. Before screening is initiated, hypokalemia should be corrected and all contraindicated medications discontinued. Although patients can continue the majority of antihypertensive agents during screening, mineralocorticoid receptor antagonists are contraindicated and should be stopped at least 6 weeks before testing (Seifarth et al, 2002; Young, 2007a). Patients requiring these agents for control of severe hypertension should be transitioned to agents, such as α_1 -receptor blockers or long-acting calcium channel blockers, with minimal effects on screening test results (Rossi et al, 2008a). Other antihypertensive agents can alter screening values, but not to the extent that mandates their discontinuation (see Fig. 65-32, later).

Screening for primary aldosteronism begins by obtaining a morning (between 8 and 10 AM) plasma aldosterone concentration (PAC) and PRA (Funder et al, 2008). From these tests, the PAC and aldosterone-to-renin ratio (ARR) are used to screen for autonomous aldosterone secretion. Whereas the ARR is dependent on PRA, it is recommended that the lowest PRA value be set at 0.2 ng/mL/hr to avoid falsely elevated ratios (Rossi et al, 2006a). The PACs and ARRs that define a positive screen and suggest the diagnosis of primary aldosteronism are subject to laboratory variability; thus, standard thresholds have not been established. Reported sensitivities and specificities for use of ARRs in screening for primary aldosteronism range from 66% to 100% and 61% to 96%, respectively (Jansen et al, 2014). The National Institutes of Health (NIH) Consensus Statement (2002) on the management of the clinically inapparent adrenal mass suggests cutoffs of greater than 30 for the ARR and greater than 20 ng/dL for the PAC. However, other institutions have recommended lowering the cutoffs to greater than 20 and greater than 15 ng/dL, respectively (Young, 2007a; Rossi et al, 2008a). Although lowering the thresholds for a positive screening test result may increase the rate of false positives, all positive test results must be confirmed with further testing before the diagnosis of primary aldosteronism is made.

Measurement of PRA can be time-consuming and varies among different laboratories. For this reason, plasma renin concentration has been evaluated as a possible replacement for PRA in screening for primary aldosteronism (Ferrari et al, 2004; Perschel et al, 2004). Although initial series evaluating the usefulness of plasma renin concentration in primary aldosteronism screening have demonstrated promise, these findings require further standardization and validation before widespread use (Young, 2007a; Rossi et al, 2008b). **Confirmatory Testing.** After a positive screening test result, a confirmatory test must be performed before the diagnosis of primary aldosteronism is secured, owing to the known variability of aldosterone and PRA levels secondary to day-to-day oscillation, posture, diet, and antihypertensives (Salva et al, 2012). Of patients with positive screening test results, only 50% to 87% will be diagnosed with primary aldosteronism on confirmatory testing (Mosso et al, 2003; Seiler et al, 2004; Giacchetti et al, 2006; Nanba et al, 2012). As with screening for primary aldosteronism, proper patient preparation is required, with the correction of hypokalemia and discontinuation of mineralocorticoid receptor antagonists. Of the confirmatory tests available, the majority evaluate the suppression of aldosterone after sodium loading. The underlying theory behind the sodium loading tests is that loading will decrease plasma renin and aldosterone production in patients without autonomous aldosterone secretion (Mattsson and Young, 2006). Additional confirmatory tests, including captopril suppression test, furosemide-upright test, and the ACTH stimulation test, have been described but are not widely accepted or used (Hirohara et al, 2001; Sonoyama et al, 2011). The selection of the confirmatory test used depends on individual patient characteristics and physician preferences. Blood pressure should be monitored closely in all patients during confirmatory testing.

The fludrocortisone suppression test requires the administration of the synthetic mineralocorticoid fludrocortisone (0.1 mg every 6 hours) and sodium chloride (2 g every 8 hours) for 4 days. After 4 days of fludrocortisone and sodium loading, PAC is measured in the upright position. Failure to suppress PAC to less than 6 ng/dL is diagnostic of primary aldosteronism. Once considered

the gold standard in the diagnosis of primary aldosteronism, the fludrocortisone suppression test has been supplanted by the oral sodium loading test and the intravenous infusion test owing to the risks of severe hypertension and hypokalemia (Schirpenbach and Reincke, 2007).

The oral sodium loading test is conducted by administering a high-sodium diet for 3 days, followed by 24-hour urine measurements of aldosterone, sodium, and creatinine. Supplemental sodium chloride can be given to ensure the intake of at least 12.8 g of sodium per day. Twenty-four-hour sodium should be greater than 200 mmol to ensure adequate sodium loading. The diagnosis of primary aldosteronism is then made when the 24-hour aldosterone is greater than 12 µg/day.

The intravenous saline infusion test spares the patient from several days of sodium loading by the administration of 2 L of 0.9% sodium chloride intravenously over 4 hours. The infusion is performed in the morning after an overnight fast, while the patient is in a recumbent position. After the intravenous infusion of saline, PAC is measured; a level greater than 5 ng/dL is diagnostic of primary aldosteronism, and levels greater than 10 ng/dL are suggestive of aldosterone-producing adenomas (Mulatero et al, 2005; Young, 2007a).

The captopril suppression test evaluates for the suppression of the ARR after the administration of an ACE inhibitor. Measurement of PAC is performed after administration of 25 to 50 mg of the ACE inhibitor captopril while the patient remains recumbent. Suppression of the RAAS should be noted in patients without primary aldosteronism after the administration of captopril, whereas those with autonomous aldosterone secretion will have persistently elevated PACs greater than 15 ng/dL (Young and Klee, 1988). Further standardization and validation of the captopril suppression test are needed before it is used routinely when sodium loading tests are available and not contraindicated as in patients with cardiac and renal disease, which largely prohibit sodium loading (Giacchetti et al, 2008).

Subtype Differentiation. After diagnosis of primary aldosteronism, attention is then paid to defining the cause of autonomous aldosterone secretion. Subtype differentiation of primary aldosteronism is essential in selecting the appropriate therapy, because surgical therapy is successful for only select subtypes (Box 65-3). In patients who are not surgical candidates, subtype differentiation is of little consequence because medical therapy will be instituted; thus these patients can forgo further evaluation, and medical management can be initiated (Fig. 65-13). Given the rarity of familial primary aldosteronism, genetic screening should not be performed in all patients. However, patients with a family history of primary aldosteronism, early age of onset (<20 years), or with a family history of cerebral vascular accidents at a young age should be considered for genetic testing (Fig. 65-14). Cross-sectional abdominal imaging should be performed in all patients with primary aldosteronism who are potential surgical candidates.

BOX 65-3 Subtypes of Primary Aldosteronism

SURGICALLY CORRECTABLE

Aldosterone-producing adenoma
Primary unilateral adrenal hyperplasia
Ovarian aldosterone-secreting tumor
Aldosterone-producing carcinoma

NOT CORRECTABLE BY SURGERY

Bilateral adrenal hyperplasia
Familial hyperaldosteronism type I
Familial hyperaldosteronism type II
Familial hyperaldosteronism type III

Although imperfect in delineating the subtype of primary aldosteronism, an adrenal CT scan should be obtained to evaluate for the presence of adrenal nodules. Radiographic characteristics of aldosterone-producing adenomas include the presence of a unilateral low-density nonenhancing lesion of less than 10 Hounsfield

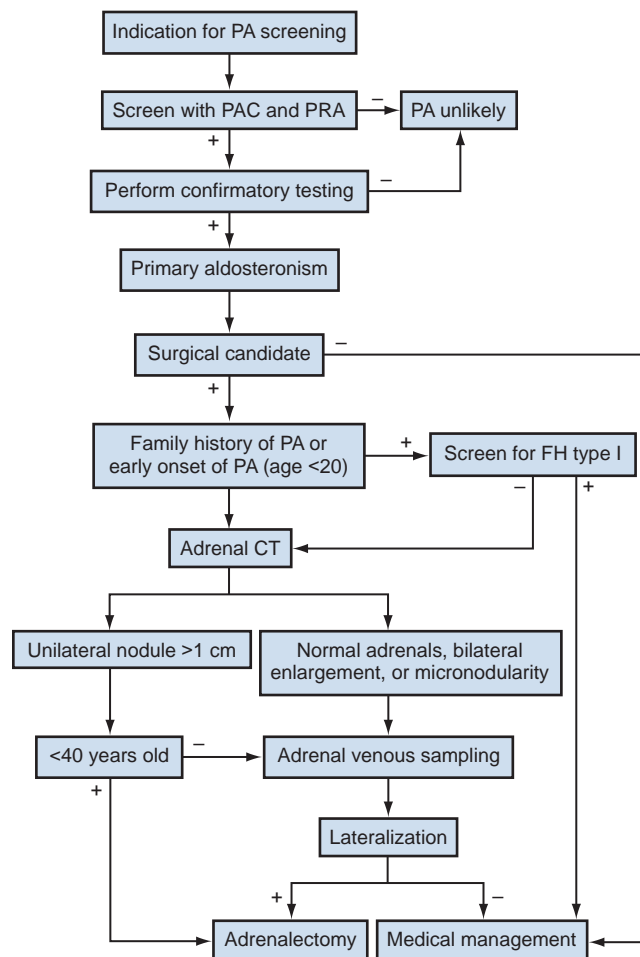

Figure 65-13. Primary aldosteronism diagnosis and treatment algorithm. CT, computed tomography; FH, familial hyperaldosteronism; PA, primary aldosteronism; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

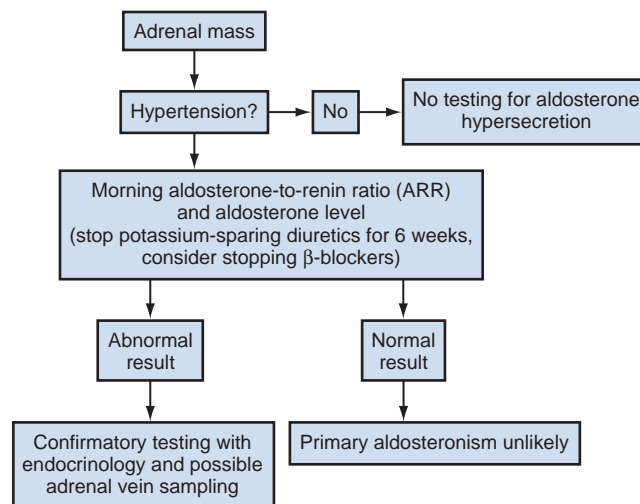

Figure 65-14. Testing algorithm for aldosterone hypersecretion by an adrenal mass.

units (HU), with an average size of 1.6 to 1.8 cm and a normal-appearing contralateral adrenal gland. However, given that approximately 20% of aldosterone-producing adenomas will be smaller than 1 cm, lateralization is not based on CT findings alone (Simon and Palese, 2008). Radiographic characteristics of idiopathic hyperplasia can include the presence of multiple unilateral or bilateral adrenal nodules, bilateral adrenal enlargement with increased limb size, or the presence of normal-appearing glands. The combination of the small-size, aldosterone-producing adenomas and the potential for the presence of nonfunctional adrenal adenomas makes CT imaging flawed in delineating lateralization of aldosterone hypersecretion. Because MRI does not offer an advantage in delineating primary aldosteronism subtypes and is associated with increased cost, routine use is not currently recommended.

To establish lateralization of aldosterone secretion in surgical candidates, adrenal vein sampling should be performed. By establishing lateralization, one can differentiate between subtypes of primary aldosteronism and identify patients in whom adrenalectomy is potentially beneficial. The value of adrenal vein sampling in evaluating the presence of lateralized aldosterone secretion was illustrated by Young and colleagues (2004), who noted that 22% of patients would have been incorrectly excluded from adrenalectomy, and 25% would have been inappropriately recommended to undergo adrenalectomy based on CT findings instead of adrenal vein sampling studies. As with all other evaluations performed for primary aldosteronism, proper patient selection, proper patient preparation, and an accurate interpretation of results are essential (Young and Stanson, 2009). A decision-making strategy when performing adrenal vein sampling is depicted in Figure 65-15.

Patients with confirmed PA should undergo adrenal vein sampling when adrenalectomy is being considered. Exceptions include patients younger than 40 years with a clear unilateral adrenal adenoma and normal contralateral adrenal gland on cross-sectional imaging and patients suspected of having an ACC (Rossi et al, 2014). Because the results of adrenal vein sampling can be affected by multiple factors, attention to preprocedural and procedural details is mandatory. Proper patient preparation is essential and includes 1 hour of recumbency, correction of hypokalemia, and discontinuation of antihypertensive agents, which may affect aldosterone and renin levels. After appropriate patient selection and preparation, adrenal vein sampling is performed in the morning after an overnight fast. Percutaneous access to the femoral vein is obtained, and catheter tips are positioned to collect samples from three sites: the right adrenal vein, left adrenal vein, and IVC (see Fig. 65-15A). Samples are then evaluated for aldosterone and cortisol concentrations. Appropriate specimen collection from the adrenal vein is determined by comparing the cortisol concentrations from the adrenal vein samples with the cortisol concentration from the IVC sample. The ratio of adrenal vein cortisol to IVC cortisol should be greater than 1:1 to 5:1, depending on the use of cosyntropin stimulation (Young and Stanson, 2009). If cosyntropin stimulation is used, a higher ratio is expected in properly collected samples. Adrenal vein sampling that demonstrates adrenal vein-to-IVC ratios below the cutoff, on either side, should be considered “nonselective” and discarded. An adrenal vein-to-IVC ratio above the cutoff, bilaterally, is considered “selective,” and comparisons between aldosterone concentrations can be made to determine the presence of lateralization.

Figure 65-15. Adrenal vein sampling protocol. **A**, Proper catheter positioning for sampling right adrenal vein sample (R), left adrenal vein sample (L), and inferior vena cava (I) sample. **B**, After sample collection, the cortisol gradient is evaluated using the ratios $R_{\text{cortisol}}/I_{\text{cortisol}}$ and $L_{\text{cortisol}}/I_{\text{cortisol}}$. If the cortisol gradients confirm appropriate sample collection, lateralization of aldosterone secretion can be evaluated. Lateralization of aldosterone secretion is determined by the ratio of aldosterone secretion of the dominant to the nondominant adrenal gland while correcting for ipsilateral cortisol secretion using the formula $(A_{\text{dominant}}/C_{\text{dominant}})/(A_{\text{nondominant}}/C_{\text{nondominant}})$, where A = plasma aldosterone concentration and C = cortisol. ACTH, adrenocorticotropic hormone.

Lateralization of aldosterone secretion is determined by comparing the aldosterone-to-cortisol ratios of the dominant to nondominant sides using the formula $(A_{\text{dominant}}/C_{\text{dominant}})/(A_{\text{nondominant}}/C_{\text{nondominant}})$. Aldosterone secretion is considered to be lateralized if the ratio is greater than 2:1 to 4:1, depending on the use of cosyntropin stimulation (Young and Stanson, 2009; Rossi et al, 2014). When performed and interpreted correctly, adrenal vein sampling has a sensitivity of 95% and a specificity of 100% in detecting lateralized autonomous aldosterone secretion (Young et al, 2004).

The routine use of cosyntropin stimulation during adrenal vein sampling is controversial. Potential advantages of cosyntropin stimulation include minimizing stress-induced fluctuations in aldosterone secretion, maximizing the cortisol gradient, and maximizing the aldosterone secretion from aldosterone-producing adenomas (Young, 2007a; Young and Stanson, 2009; Rossi et al, 2014). In a prospective study investigating these potential benefits, cosyntropin stimulation was noted to facilitate the ascertainment of proper specimen collection for evaluation of the cortisol gradient between adrenal and IVC specimens. However, the authors also noted that cosyntropin stimulation was also associated with a small risk (3% to 12%) of incorrectly assigning the side of lateralization of aldosterone-producing adenomas, and a moderate risk (36% to 37%) of incorrectly classifying aldosterone-producing adenomas as idiopathic hyperplasia (Seccia et al, 2009).

When adrenal vein sampling is inconclusive because of sampling error, alternative studies are available that may help guide treatment decisions, including nuclear scintigraphy, postural stimulation testing, and measurement of cortisol metabolites. Of these modalities, only nuclear scintigraphy can provide both functional and anatomic data, which are necessary when considering surgical intervention.

Iodine-131 (^{131}I)-6 β -iodomethyl-norcholesterol (NP59) is a cortisol analog that can label adrenal cortical cells to evaluate for areas of hypersecretion (Heinz-Peer et al, 2007). Before injection of the radiotracer, saturated potassium iodine (Lugol solution) is administered to protect the thyroid from uptake of free ^{131}I . In addition, suppression of ACTH with dexamethasone (1 mg every 6 hours for 7 days) is necessary. Evaluation of radiotracer uptake is begun 4 days after NP59 injection and may continue through day 10. Characteristics that suggest the presence of aldosterone-producing adenomas include unilateral uptake of radiotracer less than 5 days after injection, whereas bilateral uptake is suggestive of idiopathic hyperplasia (Simon and Palese, 2008). The ability to detect a hyperfunctioning adenoma using NP59 is directly proportional to the tumor size and function, with a diminished ability to detect lesions smaller than 1.5 cm (Hogan et al, 1976; Nomura et al, 1990; Mansoor et al, 2002). To overcome some of the known limitations of NP59 imaging, NP59 single-photon emission computed tomography (SPECT-CT) has been evaluated and has demonstrated improved sensitivity in detecting smaller adenomas (Yen et al, 2009).

The posture stimulation test is designed to distinguish between aldosterone-producing adenomas and idiopathic hyperplasia based on changes in PAC levels in response to changes in posture. The test is performed by comparing PAC levels after the patient has been recumbent overnight, and again after 4 hours of being upright. In theory, the increase of angiotensin induced with being upright leads to an increase of PAC in normal patients that is twofold to fourfold greater when compared with recumbent levels. In comparison, patients with idiopathic hyperplasia will demonstrate an increase of at least 33% over baseline, and patients with aldosterone-producing adenomas or FH type I will not demonstrate an increase in PAC levels with changes in posture (Ganguly et al, 1973; Young, 2007a). Although the test can be helpful in distinguishing between aldosterone-producing adenomas and idiopathic hyperplasia, it does not provide information regarding the location of the adenoma (right vs. left). In addition, the reliability of the posture stimulation test is limited by the observation that 30% to 50% of aldosterone-producing adenomas demonstrate an increase of PAC, whereas 20% of idiopathic hyperplasia patients do not demonstrate any elevation

with postural changes (Mulatero et al, 2004; Schirpenbach and Reincke, 2007).

Another potential method for differentiating aldosterone-producing adenomas from idiopathic hyperplasia is the measurement of 18-hydroxycorticosterone (18-OHB). 18-OHB is formed by the 18-hydroxylation of corticosterone and may be the immediate precursor of aldosterone (Mulatero et al, 2013). Elevated 18-OHB (>100 ng/dL) suggests an aldosterone-producing adenoma, whereas levels below 100 ng/dL suggest idiopathic hyperplasia (Biglieri and Schambelan, 1979). However, the accuracy of this test in distinguishing aldosterone production from an adenoma versus hyperplasia is thought to be less than 80%. In addition, the test does not provide information about tumor location (right vs. left) in cases of functional adenomas (Young and Klee, 1988).

Treatment and Prognosis. The goal of treatment in primary aldosteronism is to control and prevent the morbidity associated with mineralocorticoid excess. Therefore the treatment strategies used in therapy aim to remove the source of mineralocorticoid excess or block the effect of aldosterone on target organs (Young, 2007a). Treatment strategies for primary aldosteronism are primarily dependent on subtype classification and surgical candidacy (see Fig. 65-13). Patients who are acceptable surgical candidates and have been diagnosed with a surgically correctable subtype of primary aldosteronism can be offered unilateral adrenalectomy; other patients can be managed effectively with medical therapy.

In patients with confirmed lateralizing aldosterone secretion, adrenalectomy should be considered. Given the small size of aldosterone-producing adenomas, the majority of patients are candidates for a laparoscopic adrenalectomy. In patients suspected of having hypersecretion of aldosterone associated with ACC, an open procedure may be recommended (Kebebew et al, 2002; Gonzalez et al, 2005; Schlamp et al, 2007). Improvements in blood pressure are noted in the majority of patients undergoing adrenalectomy for primary aldosteronism, with 33% to 73% of patients not requiring antihypertensives postoperatively (Sawka et al, 2001; Meyer et al, 2005; Schirpenbach and Reincke, 2007). Several predictors of persistent hypertension after adrenalectomy for primary aldosteronism have been described, including age older than 50 years, male gender, high body mass index, the use of two or more antihypertensive agents preoperatively, having a first-degree relative with hypertension, prolonged duration of hypertension before adrenalectomy, degree of cardiovascular remodeling, and renal insufficiency (Celen et al, 1996; Sawka et al, 2001; Wang et al, 2012; Rossi et al, 2014). In patients younger than 40 years with a unilateral adenoma larger than 1 cm, a unilateral adrenalectomy can be performed without adrenal vein sampling because of the rarity of incidental adenomas in this population (Schirpenbach and Reincke, 2007; Young, 2007a; Zarnegar et al, 2008). In the immediate postoperative period, PAC and ARR should be evaluated to ensure biochemical cure. In addition, patients should maintain a high-sodium diet and be monitored for hyperkalemia for several weeks after surgery (Mattsson and Young, 2006; Funder et al, 2008).

Medical treatment of primary aldosteronism is indicated in patients with nonsurgically correctable subtypes and those who are not surgical candidates. The aldosterone receptor antagonists spironolactone and eplerenone are successful in lowering the blood pressure and are the antihypertensive agents of choice in patients with primary aldosteronism. Spironolactone therapy is initiated at doses of 25 to 50 mg/day and can be titrated up to 400 mg/day, depending on blood pressure, serum potassium levels, and side effects. Side effects of spironolactone include gynecomastia, impotence, and menstrual disturbances. Eplerenone may provide a more favorable side-effect profile compared with spironolactone owing to increased selectivity for the aldosterone receptor. Treatment should be initiated with 25 mg per day and titrated up to 100 mg/day. Despite treatment with an aldosterone receptor antagonist, other antihypertensive agents will often be needed. In addition, several lifestyle modifications may contribute to the success of medical therapy, including weight loss, a low-sodium diet, and a regular exercise program (Young, 2007a).

Unlike other forms of primary aldosteronism, FH type I can be treated with oral glucocorticoids. Glucocorticoid administration will reduce ACTH release, leading to decreased aldosterone production in this select group of patients. In FH type I patients whose blood pressure is not controlled with glucocorticoids alone or in those who develop iatrogenic Cushing syndrome, the addition of an aldosterone receptor antagonist should be considered (Funder et al, 2008).

Summary. Successful identification and treatment of primary aldosteronism is critical because of the increased risk of cardiovascular morbidity associated with the diagnosis. Because primary aldosteronism consists of several distinct subtypes that significantly affect management strategy, subtype differentiation is critical before surgical intervention.

KEY POINTS: PRIMARY ALDOSTERONISM

- Most patients with primary aldosteronism in contemporary series are normokalemic.
- Primary aldosteronism is associated with an increased risk of end-organ damage compared with essential hypertension.
- Accurate subtype differentiation is essential to ensure appropriate treatment of primary aldosteronism.

Pheochromocytoma

Overview and Epidemiology. Pheochromocytoma is a tumor of the catecholamine-producing cells of the adrenal medulla. Approximately 1 to 2 per 100,000 individuals are diagnosed annually with pheochromocytoma, albeit reports on incidence vary (Bravo and Tagle, 2003). Given its rarity, it is estimated that pheochromocytoma is responsible for only approximately 0.5% of cases of hypertension (Lenders et al, 2005). Among patients with incidental adrenal masses, approximately 5% will have a pheochromocytoma (Mantero et al, 2000; Young, 2000). Indeed, incidentally discovered lesions now account for 10% to 25% of all pheochromocytomas diagnoses (Bravo and Tagle, 2003; Lenders et al, 2005).

Some 1% to 25% of pheochromocytomas originate outside of the adrenal gland (Fig. 65-16). These extra-adrenal pheochromocytomas are known as *paragangliomas*, because they arise from paraganglia, a network of chromaffin-producing neural crest tissue that anatomically parallels the sympathetic and parasympathetic ganglia (Scott et al, 1990; Ilias and Pacak, 2004). Paragangliomas can arise in the head, neck, thorax, abdomen, and pelvis (including bladder). The chromaffin bodies that lie between the aortic bifurcation and the root of the inferior mesenteric artery are known as the *organ of Zuckerkandl* and are a common site for paragangliomas (Scott et al, 1990). Of note, some authors reserve the term *paraganglioma* for tumors only in the head and neck, locations where extra-adrenal pheochromocytomas tend to be nonfunctional (Neumann et al, 2004).

Pathophysiology

Overview. As discussed in the section on adrenal physiology, cells of the adrenal medulla are analogous to the chromaffin cells of the

sympathetic ganglia. Unlike sympathetic ganglia cells, however, cells of the adrenal medulla, and therefore of adrenal pheochromocytomas, possess the enzyme PNMT, which gives them the ability to synthesize epinephrine from norepinephrine (Eisenhofer et al, 2004b). Pheochromocytomas vary in their enzymatic composition and in their ability to self-metabolize the catecholamines within each tumor's secretory vesicles. Therefore there is great variability in the amount and ratio of catecholamines secreted by pheochromocytomas (Eisenhofer et al, 2001). Indeed, these differences in norepinephrine, epinephrine, and dopamine secretion explain the heterogeneity in clinical behavior of pheochromocytomas. For instance, patients with the rare tumors that secrete primarily epinephrine (usually limited to those that arise from the adrenals or from the organ of Zuckerkandl) tend to experience syncopal or hypotensive episodes because of epinephrine's vasodilatory action through the β_2 receptor, whereas patients with predominantly norepinephrine-secreting tumors (e.g., patients with von Hippel-Lindau [VHL] syndrome) have hypertension and sweating, given the compound's affinity for the vasoconstricting α adrenoreceptor (Pacak, 2007).

Pathophysiology of Hereditary Pheochromocytoma. Familial cases account for nearly one third of pheochromocytomas (Benn and Robinson, 2006). Indeed, a significant percentage of cases that initially appear sporadic are later deemed hereditary on genetic testing. In a 2002 report, Neumann and colleagues (2002) demonstrated that 24% of patients ($n = 271$) with isolated pheochromocytoma who lacked any significant family history exhibited a germline mutation that predisposed them to the disease. At least five genes—rearranged transfection proto-oncogene (*RET*), von Hippel-Lindau (*VHL*), neurofibromatosis type 1 (*NF1*), and mitochondrial succinate dehydrogenase subunits D and B genes (*SDHD*, *SDHB*)—are now associated with familial pheochromocytomas. Some investigators believe that these genetic abnormalities all modulate neuronal apoptosis and are related through signal transduction pathways downstream from the nerve growth factor (NGF) (Nakamura and Kaelin, 2006). Nevertheless, the phenotypes produced by each gene mutation are quite diverse. Table 65-6 summarizes the clinical features associated with each gene mutation.

In general urologic practice, VHL is the most relevant syndrome associated with pheochromocytoma, because these patients usually are already under urologic care owing to their propensity to develop renal cell carcinoma (RCC). Patients with VHL and no family history of pheochromocytoma are classified as having the type 1 variant of the syndrome, whereas type 2 patients are those who carry a family history of pheochromocytoma. In addition, the type 2 variant of VHL is further subdivided. Type 2A patients are those without concomitant RCC, and type 2B patients are those who do exhibit evidence of renal malignancy (Linehan and Ricketts, 2013). A type 2C variant is defined as patients with pheochromocytoma in the setting of a *VHL* mutation, but no other stigmata of the VHL syndrome (Hes et al, 2003). It is interesting to note that a genotype phenotype has been established with VHL-associated pheochromocytomas (type 2), wherein these patients are more likely to exhibit a missense mutation of the *VHL* gene (Walther et al, 1999). Whereas VHL type 2C patients appear to maintain hypoxia-inducible factor (HIF) regulation, pheochromocytoma pathogenesis may occur through HIF-independent pathways (Nakamura and Kaelin, 2006). Furthermore, pheochromocytomas in patients with VHL, unlike those in cases of sporadic or multiple endocrine neoplasia type 2 (MEN-2)-related disease, tend to produce less epinephrine. As a result, metanephrine (but not normetanephrine) levels in these patients are nearly always normal (Eisenhofer et al, 1999; Walther et al, 1999; Pacak, 2007).

Pathophysiology of Malignant Pheochromocytoma. Malignant pheochromocytoma is an aggressive life-threatening neoplasm. Currently, malignancy can only be defined by the presence of clinical metastases. Pathologic appearance and even local invasion are of only limited value in determining metastatic potential of a given lesion (Scholz et al, 2007). A number of pathologic criteria to differentiate benign from malignant disease have been proposed, but to date there is no single histologic criterion agreed

Figure 65-16. Causes of excess catecholamines.

on (Thompson, 2002; Kimura et al, 2005; Pacak et al, 2007; Scholz et al, 2007). Some pathologic criteria use immunohistochemical strategies including Ki-67 staining, which may be the best indicator of malignancy thus far, although it has not yet been validated owing to methodologic heterogeneity (Kimura et al, 2005; Pacak et al, 2007).

Malignant pheochromocytoma in patients with MEN-2 and VHL is exceedingly rare (see Table 65-6). The *SDHB* mutation is the single genetic abnormality most strongly associated with malignancy. In one international series, 11 of 32 patients with this mutation exhibited clinically malignant pheochromocytoma (Neumann et al, 2004).

Clinical Characteristics

Overview. Classically, pheochromocytoma has been called the “10% tumor”: 10% extra-adrenal, 10% familial, 10% bilateral, 10% pediatric, and 10% malignant (Scott et al, 1990; Dluhy, 2002; Lenders et al, 2005). However, this rule has been challenged repeatedly. As already mentioned, up to 25% of pheochromocytomas can be extra-adrenal (Ilias and Pacak, 2004). Similarly, familial cases account for up to 30% of tumors at presentation (Benn and Robinson, 2006). Malignancy is rare in both sporadic cases of adrenal pheochromocytoma (up to 5%) and in most cases of hereditary disease (see Table 65-6). However, for unclear reasons, it occurs in over one third of patients with extra-adrenal disease (Lenders et al, 2005). Nonhereditary cases of pheochromocytoma are most often diagnosed in the fourth and fifth decades of life, whereas familial tumors tend to occur at a younger age (Lenders et al, 2005). Despite being uncommon, pediatric pheochromocytoma is the most frequently encountered endocrine neoplasm in children. Up to 40% of such tumors are familial, and over 20% are bilateral (Pacak et al, 2007; Havekes et al, 2009). For reasons that are unclear, tumors arising from the right adrenal are more common, tend to be larger, and recur more frequently than those that arise in the left gland (Amar et al, 2005b).

Paroxysmal hypertension is the classic presenting sign in patients with pheochromocytoma. Nevertheless, such episodic spikes in blood pressure are documented in only approximately 30% to 50% of patients and can occur in the backdrop of baseline essential hypertension. The remainder of patients demonstrate persistently elevated blood pressure, and a minority are entirely normotensive (Scott et al, 1990). The triad of headache, episodic sudden perspiration, and tachycardia is a classic hallmark of pheochromocytoma (Bravo and Tagle, 2003). Table 65-7 lists common clinical signs and symptoms of pheochromocytoma. More than 20% of patients can be asymptomatic (Adler et al, 2008). Indeed, depend-

ing on the catecholamine milieu of each tumor, its ability to self-metabolize the catecholamine reserve, and patients' varied responses to catecholamine surges, symptomatology can drastically differ from patient to patient (Pacak, 2007). This heterogeneity in mode of presentation and symptomatology and the difficulty in establishing firm diagnostic criteria for pheochromocytoma are illustrated by an autopsy series that included 54 patients over a 50-year period from the Mayo Clinic, wherein more than 75% of tumors were not suspected before the patient's death (Sutton et al, 1981).

Clinical Characteristics of Hereditary Pheochromocytoma. Hereditary pheochromocytomas occur at a younger age and tend to be multifocal and/or bilateral at presentation (Adler et al, 2008). Table 65-6 summarizes the clinical features of each gene mutation. Pheochromocytomas in patients with MEN-2 nearly always arise from the adrenal gland, whereas tumors in patients with VHL and neurofibromatosis type 1 (NF-1) are outside the adrenal in approximately 12% and 6% of cases, respectively (Lairmore et al, 1993; Walther et al, 1999; Benn and Robinson, 2006; Karagiannis et al, 2007). *SDHB* and *SDHD* mutations mostly result in extra-adrenal and often multifocal phenotypes; nevertheless, solitary adrenal masses, as a result of these genetic abnormalities, may also arise (Neumann et al, 2004; Pacak et al, 2007). Unlike other hereditary forms of pheochromocytoma, mutations in the *SDHB* gene are associated with a very high risk of malignancy (Neumann et al, 2004). As mentioned previously, pheochromocytomas in patients with VHL mainly secrete norepinephrine and lack significantly elevated epinephrine secretion. As a result, normetanephrine, but not metanephrine, levels are elevated in these patients (Eisenhofer et al, 1999; Walther et al, 1999; Pacak, 2007).

Clinical Characteristics of Malignant Pheochromocytoma. Metastatic disease is much more common in extra-adrenal lesions (Scholz et al, 2007). The *SDHB* mutation is the one genetic abnormality that is strongly associated with metastatic disease (see Table 65-6). Classically, the majority of patients with an *SDHB* abnormality exhibit extra-adrenal disease; however, a significant proportion of patients (28% of patients in one series) have adrenal lesions at presentation (Neumann et al, 2004). Malignant lesions are more likely to exhibit elevated dopamine levels and tend to be larger (>5 cm); however, as mentioned previously, in the absence of metastatic deposits, a preclinical diagnosis of malignant potential is not possible (John et al, 1999; Lenders et al, 2005). Bone, lungs, liver, and lymph nodes constitute the most common sites of metastases (Scholz et al, 2007).

Metastatic pheochromocytoma can be present at diagnosis or be detected during surveillance after excision of the primary tumor. Most metastases are discovered within 5 years of the original diagnosis, but metastatic spread more than 15 years after initial excision has been reported (Eisenhofer et al, 2004a; Lenders et al, 2005).

Diagnostic Tests. Biochemical testing is the first step in the evaluation of patients suspected of having pheochromocytoma. If metabolic testing results are positive, appropriate imaging is undertaken to localize the source of the catecholamine excess (Adler et al, 2008). Timely and appropriate diagnosis of pheochromocytoma continues to be a clinical challenge (Zendron et al, 2004; Harding et al, 2005; Yu et al, 2009). In urologic practice, diagnosis of pheochromocytoma typically begins with the evaluation of an adrenal mass as a catecholamine-hypersecreting lesion. Given the potentially catastrophic consequences of misdiagnosis, the possibility of pheochromocytoma must also be considered in patients with a known history of malignancy, and with a solitary adrenal mass in those in whom a metastatic adrenal lesion is suspected (Weismann et al, 2006; Adler et al, 2007). Clinical evaluation depends on both radiographic imaging and, more important, biochemical testing.

Imaging. Here we briefly discuss imaging of pheochromocytoma. Please refer to the section on imaging of adrenal masses for further details on adrenal imaging.

Cross-Sectional Imaging. On cross-sectional imaging, adrenal pheochromocytomas appear as well-circumscribed lesions. Given their rich vascularity and low lipid content, pheochromocytomas typically measure an attenuation of greater than 10 HU on unenhanced CT (mean approximately 35 HU). This property affords

TABLE 65-7 Clinical Manifestations of Pheochromocytoma

MANIFESTATION	FREQUENCY (%)
Headache	60-90
Palpitations	50-70
Sweating	55-75

Figure 65-17. Imaging of pheochromocytoma. A, Axial T2-weighted magnetic resonance image of a right adrenal mass that proved to be pheochromocytoma. B, Metaiodobenzylguanidine (MIBG) scan of a different patient with a localized left pheochromocytoma. Normal uptake can be seen in the liver, salivary glands, thyroid, and bladder. It is important to note that fluorodeoxyglucose positron emission tomography appears to be superior to the MIBG scan with a notable exception of patients with known multiple endocrine neoplasia type 2 (A, Courtesy Dr. Rosaleen Parsons, Fox Chase Cancer Center, Philadelphia; B, courtesy Dr. Michael Yu, Fox Chase Cancer Center, Philadelphia.)

the ability to differentiate them from lipid-rich adenomas (Motta-Ramirez et al, 2005). Furthermore, pheochromocytomas can be distinguished from lipid-poor adenomas through use of CT contrast washout strategies. Although nonspecific, pheochromocytomas, unlike adenomas, do not exhibit rapid contrast washout on delayed imaging (Szolar et al, 2005); rare examples of low-density pheochromocytomas that exhibit an unenhanced attenuation of less than 10 HU and demonstrate brisk contrast washout have been reported (Blake et al, 2003, 2005). Such examples underscore the importance of a complete metabolic evaluation for every adrenal mass. In the past, iodinated intravenous contrast was believed to be a possible trigger for a hypertensive crisis. No evidence exists to support this misconception (Pacak, 2007).

Similar to CT, MRI is an excellent imaging modality for characterizing adrenal lesions. Again, differentiation of pheochromocytoma from adenoma centers on an assessment of the lesion's lipid content. Unlike lipid-rich adenomas, pheochromocytomas do not exhibit signal dropout on out-of-phase sequences (Namimoto et al, 2001). Classically, bright signal intensity on T2-weighted imaging (best seen on fat suppression sequences)—termed the “light bulb” sign—was believed to be diagnostic for pheochromocytoma. It is now clear that this imaging characteristic is neither specific nor sensitive enough to secure a diagnosis and must be interpreted with caution (Varghese et al, 1997; Elsayes et al, 2005).

Functional Imaging

¹⁸F-Fluorodeoxyglucose Positron Emission Tomography. Fluorine-18 fluorodeoxyglucose positron emission tomography (¹⁸F-FDG PET) recently has emerged as the gold standard imaging modality for definitive staging in patients with pheochromocytoma. Initially ¹⁸F-FDG PET was shown to be a useful clinical tool for patients with the *SDHB* mutation (Timmers et al, 2007a, 2007b); however, a recent report of over 200 patients with adrenal and extra-adrenal pheochromocytoma from investigators from the NIH documented that ¹⁸F-FDG PET has far superior test characteristics to CT, MRI, and metaiodobenzylguanidine (MIBG) scintigraphy. ¹⁸F-FDG PET exhibited better accuracy than ¹²³I-MIBG in nearly all patients, especially for identification of metastatic disease. Notable exceptions were individuals with MEN-2 germline mutations, for whom

sensitivity of ¹⁸F-FDG PET was low (<50%) and in whom the procedure was far inferior to ¹²³I-MIBG. It is interesting to note that PET avidity was independent of the tumor's biochemical vigor or “phenotype” (Timmers et al, 2012).

Metaiodobenzylguanidine Scintigraphy. MIBG is a small-molecule analog of norepinephrine. With MIBG tagged with either ¹³¹I or ¹²³I, MIBG scintigraphy has been used since the 1980s to evaluate patients with pheochromocytoma. ¹²³I-MIBG—the preferred agent—affords a high sensitivity (83% to 100%) and superb specificity (95% to 100%) for identification of pheochromocytoma (Fig. 65-17) (Ilias and Pacak, 2004). Details regarding this imaging modality are discussed in the imaging section of this chapter. Here, we review clinical applications of MIBG.

MIBG historically has been an integral part of a thorough workup for patients with extra-adrenal, metastatic, or recurrent pheochromocytoma; however, new data suggest that ¹⁸F-FDG PET may be a superior modality for non-MEN-2 patients (Timmers et al, 2007b, 2012). MIBG is also often used to localize disease in patients with biochemical evidence of pheochromocytoma but negative cross-sectional imaging. Nevertheless, currently no consensus exists on the role of MIBG in the most common and urologically most relevant clinical scenario—a solitary adrenal mass on cross sectional imaging in the setting of a biochemical evaluation indicative of pheochromocytoma (Pacak et al, 2007; Koch, 2009). Advocates for MIBG testing argue that in this context, MIBG and, more recently, ¹⁸F-FDG PET afford the opportunity to verify that the mass in question is indeed a pheochromocytoma and that metastatic disease was not missed on cross-sectional imaging (Ilias and Pacak, 2004). Some clinical data, however, suggest that MIBG or ¹⁸F-FDG PET in this situation can safely be omitted because these functional studies only serve to confirm what is already known and do not alter management (Miskulin et al, 2003; Bhatia et al, 2008; Greenblatt et al, 2008). Nevertheless, MIBG or ¹⁸F-FDG PET imaging for large (>5 cm) tumors is likely prudent to assess for presence of metastatic disease before surgery and thereby counsel the patient appropriately (Lenders et al, 2005). Rarely, MIBG scanning may also be used when metabolic workup of an adrenal mass reveals exclusive excess of norepinephrine and normetanephrine but not epinephrine or

metanephrine. In such unusual circumstances, MIBG scanning can at times demonstrate that the actual functioning lesion is extra-adrenal (Pacak et al, 2007).

Other Functional Imaging Modalities. Whole-body functional imaging with MIBG has its limitations. For instance, tumors in patients with *VHL* and *SDHB* gene mutations may exhibit cold MIBG scans (Timmers et al, 2007b; Havekes et al, 2008). ^{18}F -FDG PET, nevertheless, is exquisitely sensitive in these individuals (Timmers et al, 2012). Furthermore, aggressive metastatic lesions may lose their ability to accumulate MIBG (Havekes et al, 2008). As discussed in the section on imaging, several modalities using radiolabeled somatostatin analogs and PET radiopharmaceuticals have been developed to serve as alternatives to MIBG or ^{18}F -FDG PET in these instances. Most have limited clinical usefulness; however, PET imaging with ^{18}F -dopamine has been explored at some institutions (Timmers et al, 2007a).

Biochemical Evaluation

Overview. Catecholamines and their metabolites, including metanephrines, are conjugated with a sulfate moiety in the bloodstream. The term *free* refers to compounds that are not conjugated and lack this sulfate group. In the past, assays that measured “total” amounts of catecholamine metabolites were used. These assays were not able to discriminate between “free” and “sulfonated” compounds and were largely inferior in their test characteristics compared with current methods (Eisenhofer et al, 2003a). Moreover, in the past, assays did not always distinguish compound subtypes and reported the aggregate level of catecholamines or metanephrines. Today, the term *fractionated* is used when the laboratory report details not only the amount of each compound type (e.g., metanephrines), but also the relative concentrations of each compound (e.g., normetanephrine and metanephrine) (Eisenhofer et al, 2004b) (Table 65-8).

Catecholamine Testing. Catecholamines—dopamine, norepinephrine, and epinephrine—are produced by pheochromocytomas in varying amounts. Release of these compounds into the bloodstream is often paroxysmal. In the past, measurement of both urinary and serum catecholamine levels was the mainstay for evaluation of pheochromocytoma. Because of the sensitivity (approximately 85%) and specificity (approximately 85%) of these tests, this strategy has been largely replaced by measurements of levels of metanephrines—the methylated metabolites of catecholamines (Lenders et al, 2002, 2005). Measurement of urinary catecholamines, nevertheless, is still recommended in conjunction with urinary fractionated metanephrine testing (Young, 2007b).

Metanephrine Testing. O-methylation of catecholamines is catalyzed by the COMT enzyme. O-methylation of norepinephrine produces normetanephrine, whereas epinephrine’s methylation results in formation of metanephrine. Together, normetanephrine and metanephrine are known as *metanephrines* (see Fig. 65-4) (Eisenhofer et al, 2001). Historically, formation of metanephrines was believed to take place by COMT in the liver and kidneys after catecholamines were released into the peripheral circulation by the tumor. Now it is clear that the vast majority of metanephrine

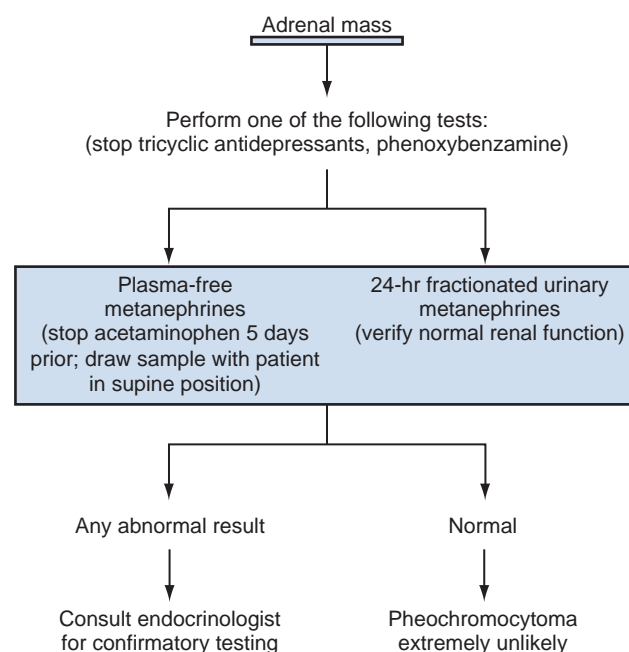

Figure 65-18. Testing algorithm to evaluate adrenal mass for catecholamine secretion.

synthesis occurs within the adrenal medulla and/or pheochromocytoma, and only then do metanephrines enter the bloodstream (Eisenhofer et al, 1998, 2004b). Because this conversion of catecholamines to metanephrines is an uninterrupted process within pheochromocytomas, measurement of plasma concentration of metanephrines is a much more sensitive means of tumor detection than the measurement of rises in plasma catecholamines, which may be paroxysmal (Eisenhofer et al, 2003a, 2003b). Today, measurement of metanephrine levels in plasma or urine represents the foundation for pheochromocytoma diagnosis and is extremely sensitive (Fig. 65-18). Controversy exists regarding whether measurement of plasma free metanephrines versus urinary fractionated metanephrines should be used as the initial test (Lenders et al, 2002; Sawka et al, 2003; Young, 2007b; Eisenhofer et al, 2008). Please refer to the section Testing for Catecholamine Hypersecretion (in the Assessment of Function of Adrenal Masses section) for a complete discussion of the two testing strategies. Traditionally, when tests for fractionated urine or total metanephrines are ordered, urine catecholamine levels are also obtained (Eisenhofer et al, 2003a).

Vanillylmandelic Acid Testing. Because VMA is the primary end metabolite of catecholamines, its measurement in urine has long been used for diagnosis of pheochromocytoma. Nevertheless, synthesis of VMA requires deamination of catecholamines, or their

metabolites, by the MOA enzyme and occurs not only in the adrenal medulla but also in the sympathetic nervous system. Moreover, the sympathetic nervous system lacks the ability to produce epinephrine owing to the absence of the PNMT enzyme and therefore contributes to the serum level of only normetanephrine (from norepinephrine) but not metanephrine (from epinephrine). Therefore the relative rise of VMA levels in the presence of a pheochromocytoma is much less dramatic than the rise seen in the levels of metanephrines, and the sensitivity of urine VMA levels is therefore low (below 65% in some series) (Lenders et al, 2005). However, the specificity of the test is high, especially in nonfamilial cases (99%) (Lenders et al, 2002).

Clonidine Suppression Testing. Clonidine, an α_2 agonist, suppresses catecholamine (specifically norepinephrine) production by the sympathetic nervous system but not by pheochromocytoma. Comparison of normetanephrine levels before and after clonidine administration has been shown to yield results with favorable test characteristics (Eisenhofer et al, 2003b). This evaluation is suggested by some experts for secondary testing in patients with pheochromocytoma who exhibit mild or borderline elevations in metanephrine levels. When embarking on clonidine suppression testing, one must be cognizant that clonidine administration can result in significant hypotension in certain patients (Eisenhofer et al, 2003b).

Chromogranin A Testing. Chromogranin A belongs to a group of compounds known as granins, which exist in the secretory vesicles of the neuroendocrine and the nervous systems. Elevation of serum chromogranin A levels has been documented in patients with pheochromocytoma. Although the sensitivity of the test for detecting pheochromocytoma is suboptimal (approximately 85%), some have suggested that the evaluation of chromogranin A level has a role in confirmatory testing in patients who have mild or moderate (less than a fourfold) elevation in free plasma metanephrine levels (Bravo and Tagle, 2003; Algeciras-Schimmich et al, 2008). Chromogranin A is renally cleared, and the specificity of the test decreases significantly in patients with glomerular filtration rates less than 80 mL/min (Bravo and Tagle, 2003).

Screening for Hereditary Pheochromocytoma. A hereditary pattern is responsible for more than one third of pheochromocytomas. Furthermore, nearly one quarter of patients who appear to have sporadic nonfamilial disease at diagnosis demonstrate germline mutations on genetic testing (Neumann et al, 2002; Benn and Robinson, 2006). Despite this, the consensus of the First International Symposium on Pheochromocytoma in 2005 did not endorse universal genetic testing in all patients diagnosed with pheochromocytoma. Instead, this panel of experts established guidelines for screening and evaluation for pheochromocytoma. Figure 65-19 summarizes how clinical history and disease characteristics at presentation should guide genetic testing. Others have suggested similar algorithms (Amar et al, 2005a). All patients younger than 50 should receive genetic testing for the *RET*, *VHL*, *SDHB*, and *SDHD* gene mutations (Pacak, 2007). Routine testing for the *NF1* gene is not recommended in patients who do not meet clinical criteria for neurofibromatosis (Plouin and Gimenez-Roqueplo, 2006b). Before initiating genetic testing, the patient should be counseled about implications and benefits of genetic testing. Professional genetic counseling is strongly recommended (Pacak, 2007).

Treatment

Overview. Pheochromocytoma is a surgical disease. Complete resection of the tumor is advised whenever possible (Khorram-Manesh et al, 2005). Laparoscopic adrenalectomy constitutes the standard of care for most tumors, although open approaches have been advocated for large and/or surgically difficult tumors (Pacak et al, 2007). Please see Chapter 66 regarding surgical considerations when treating patients with pheochromocytoma. The urologist must be familiar with the perioperative management of catecholamine-producing tumors before taking the patient to the operating room. Lifelong follow-up is necessary for all patients. Patients with familial and malignant disease require a tailored approach that should include cardiology, endocrinology, and, if needed, medical oncology.

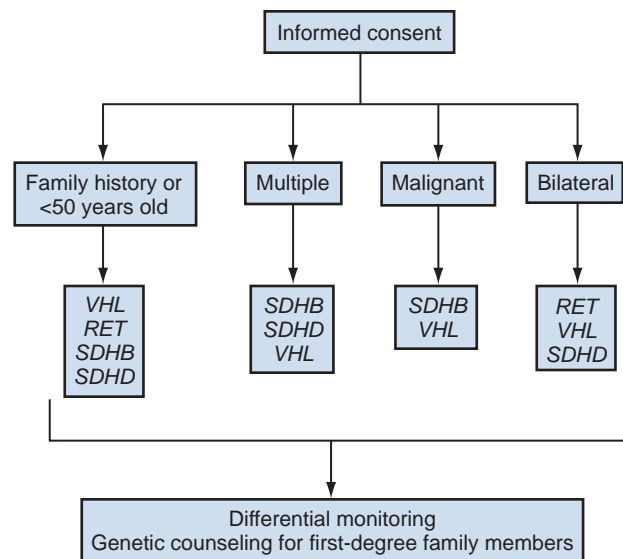

Figure 65-19. Algorithm for genetic screening of patients with pheochromocytoma with risk factors for hereditary disease. (From Pacak K. Preoperative management of the pheochromocytoma patient. J Clin Endocrinol Metab 2007;92:4069–79.)

Preoperative Management

Overview. Catecholamine release during intraoperative tumor manipulation can result in hazardous blood pressure elevation and cardiac arrhythmias. In the era before routine initiation of preoperative catecholamine blockade, some reported mortality rates as high as 50% (Pacak et al, 2001b). In 2005, the First International Symposium on Pheochromocytoma recommended that all patients with pheochromocytoma and an abnormal metabolic evaluation undergo preoperative catecholamine blockade, including patients who do not exhibit evidence of blood pressure elevation and lack classic symptomatology (Pacak, 2007). Contemporary series demonstrate mortality rates of less than 3%, which has been attributed in part to optimized anesthetic care and routine preoperative blockade (Lenders et al, 2005). In the absence of appropriately conducted clinical studies comparing preoperative management strategies, no level 1 evidence exists regarding optimal preoperative or perioperative management (Pacak, 2007). Here, we review preoperative blockade strategies relevant to aggressive α -blockade, a central theme recommended by the team from the NIH. Option 1 in Figure 65-20 summarizes the team's approach. We also outline an alternative strategy (see Fig. 65-20, option 2) that focuses on calcium channel blockade and that has been popularized by other authors (Ulchaker et al, 1999). Other permutations on approaches to preoperative catecholamine blockade exist but are less widely discussed in the literature (Pacak, 2007).

Thoughtful preoperative cardiac evaluation is paramount, because patients with pheochromocytoma are at risk for cardiomyopathy. Some experts recommend routine preoperative echocardiography (Kinney et al, 2002). We suggest that the patient undergo either a cardiology or an anesthesia consultation before surgery.

α -Blockade. Phenoxybenzamine is the most common α -blocker used for preoperative catecholamine blockade of pheochromocytoma. The agent irreversibly blocks the α receptor. Accordingly, intraoperative catecholamine surges typically do not override its actions, because reversal of the blockade is possible only through synthesis of new receptor molecules (Pacak, 2007). Phenoxybenzamine is started 7 to 14 days before surgery. Oral administration of 10 mg twice daily is initiated and titrated by increases of 10 to 20 mg to a blood pressure of 120 to 130/80 mm Hg in a seated position. Mild postural hypotension with systolic pressure greater than 80 mm Hg is acceptable (Kinney et al, 2002). Experience shows that a final dose of 1 mg/kg is usually sufficient to achieve adequate blockade (Pacak, 2007). In children,

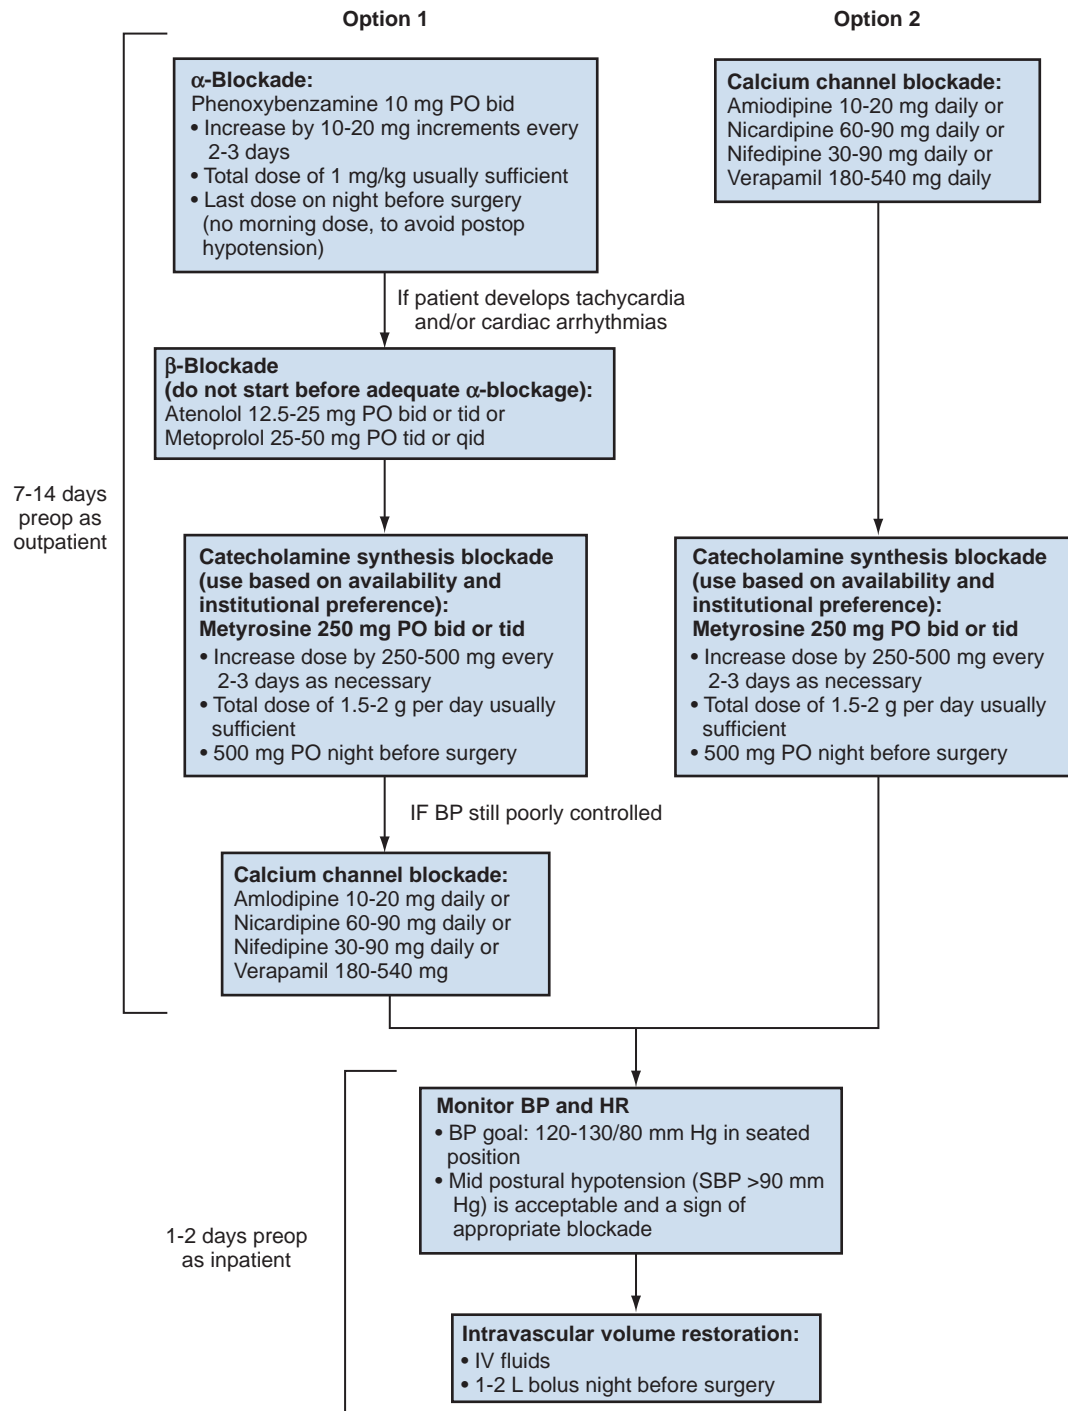

Figure 65-20. Preoperative medical management in patients with pheochromocytoma. BP, blood pressure; HR, heart rate; IV, intravenous; PO, by mouth; SBP, systolic blood pressure. (Modified from Pacak K. Preoperative management of the pheochromocytoma patient. *J Clin Endocrinol Metab* 2007;92:4069–79.)

0.2 mg/kg (maximum dose of 10 mg) four times daily with increases in 0.2-mg/kg increments is recommended (Lenders et al, 2005). Because of the irreversible nature of α -blockade, after tumor resection patients may require transient blood pressure support (Pacak, 2007).

Selective reversible α_1 -blockers, such as terazosin, doxazosin, or prazosin, are used at some centers in lieu of or in combination with phenoxybenzamine. Although these agents may have fewer side effects than phenoxybenzamine, data regarding their efficacy are contradictory (Lenders et al, 2005; Pacak, 2007). Moreover, recent compelling data are emerging that in normotensive asymptomatic

patients, preoperative α -blockade may not be necessary. In one report a large cohort of asymptomatic normotensive patients with incidentaloma and a metabolic workup suggestive of pheochromocytoma was offered either α -blockade with doxazosin ($n = 38$) or no preoperative blockade ($n = 21$) (Shao et al, 2011). No differences in blood pressure control or perioperative outcomes were seen between the two groups. The group that received doxazosin was more likely to require intraoperative administration of vasoactive agents (Shao et al, 2011). Although these data are provocative, they require validation from other centers, ideally in a prospective randomized fashion.

β -Blockade. β -Blockade should be used with caution in patients with pheochromocytoma; however, its use is at times necessary because of reflex tachycardia and arrhythmias that can result on initiation of α -blockade. It is important to understand that **β -blockade should never be started before appropriate α -blockade.** Indeed, in the absence of α -blockade, β antagonists cause a potentiation of the action of epinephrine on the α_1 receptors owing to blockade of the arteriolar dilation at the β_2 receptor. For this reason, selective β_1 adrenoreceptor blockers, such as atenolol and metoprolol, are usually preferred. Dosages for these agents are summarized in Figure 65-20 (Pacak, 2007).

Catecholamine Synthesis Blockade. α -Methyltyrosine, better known as *metyrosine*, blocks the rate-limiting step in the biosynthesis of catecholamines by inhibiting the tyrosine hydroxylase enzyme and thereby preventing the conversion of tyrosine to L-dihydroxyphenylalanine (L-DOPA) (see Fig. 65-4) (Pacak et al, 2001b). Approximately 3 days are necessary to achieve full clinical effect after initiation of this agent. Because blockade of catecholamine synthesis is incomplete, the use of metyrosine is usually coupled with α -blockade by phenoxybenzamine. Use of this agent largely depends on institutional preferences and availability. Some centers avoid routine use of this agent and reserve it for refractory or metastatic patients because of its central nervous system side effects, including sedation, mood depression, and galactorrhea. Extrapyramidal symptoms resembling parkinsonism can result and necessitate cessation of phenoxybenzamine use if present (Pacak et al, 2007). Dosage and titration strategies are summarized in Figure 65-20.

Calcium Channel Blockade. Calcium channel blockade in the context of catecholamine excess lowers blood pressure by generating smooth muscle relaxation (Ulchaker et al, 1999). The use of agents such as nicardipine has been suggested by some as an adjunct to traditional α -blockade therapy in refractory patients. Other groups, however, report that sole use of calcium channel blockers (see Fig. 65-20, option 2) is sufficient for safe pheochromocytoma resection (Ulchaker et al, 1999; Lebuffe et al, 2005). Indeed, advocates of this strategy argue that this approach avoids the reflex tachycardia and postoperative hypotension that are seen with use of phenoxybenzamine (Ulchaker et al, 1999). The team from the NIH suggests that this strategy (see Fig. 65-20, option 2) be reserved for patients with only mild symptomatology at presentation (Pacak, 2007).

Intravascular Volume Management. Restoration of intravascular volume is perhaps the most important component of preoperative management of patients with pheochromocytoma. Intake of salt and fluid is encouraged once catecholamine blockade has been initiated (Lenders et al, 2005). Moreover, most centers admit patients the day before surgery and initiate aggressive intravenous fluid resuscitation. The last dose of phenoxybenzamine and/or metyrosine is usually given on the night before surgery, and the next morning's dose is withheld. This approach minimizes potentially prolonged hypotension after tumor resection (Pacak, 2007).

Postoperative Management. In the immediate postoperative period, the patient must be actively monitored. If phenoxybenzamine was used for preoperative α -blockade, hypotension is common, given the lasting effects of the agent (Pacak et al, 2001b). Moreover, in a high catecholamine state, α_2 -adrenoreceptor stimulation inhibits insulin release. The withdrawal of this adrenergic stimulus after tumor resection may result in rebound hyperinsulinemia and subsequent hypoglycemia (Kinney et al, 2002). Hence, given the necessity for close monitoring, some experts advise overnight admission to the intensive care unit after pheochromocytoma resection (Lenders et al, 2005).

Follow-Up. Repeat metabolic testing should be performed approximately 2 weeks after adrenalectomy to document normalization of chromaffin cell function (Pacak et al, 2007). In patients in whom metanephrine levels remain elevated, MIBG imaging may be helpful. MIBG uptake by previously unseen metastases may be unveiled after resection of the primary tumor (Plouin and Gimenez-Roqueplo, 2006a).

Long-term vigilant postoperative follow-up of patients with pheochromocytoma is essential (Lenders et al, 2005; Pacak et al,

2007). Lifelong screening for recurrence is recommended by some experts, because 10-year recurrence rates are as high as 16% in some series of fully resected lesions (Amar et al, 2005b; Plouin and Gimenez-Roqueplo, 2006a). Indeed, recurrent disease has been noted in patients more than 15 years after resection of the original tumor (Plouin et al, 1997; Goldstein et al, 1999). Annual biochemical follow-up is mandatory for all patients with resected pheochromocytoma (Eisenhofer et al, 2004a; Lenders et al, 2005). No consensus on follow-up protocols exists; however, biochemical testing at 6 months after surgery, followed by annual testing, has been suggested (Pacak et al, 2001b, 2007). Postoperative cross-sectional imaging is reasonable to document tumor resection and appropriate healing of the resection bed. Need for subsequent imaging should be guided by results of biochemical testing (Pacak et al, 2001b).

Treatment of Hereditary Pheochromocytoma. Patients with hereditary pheochromocytoma require a unique approach. Given that for patients with MEN-2 and VHL, the risk of malignancy is low (see Table 65-6) whereas the risk of bilateral disease is significant, partial cortical-sparing adrenalectomy has been advocated. This strategy is used to avoid lifelong hormonal replacement, with its associated morbidity (Løvås et al, 2002; Yip et al, 2004; Diner et al, 2005). Successful surgical outcomes require advanced surgical expertise and careful preoperative radiographic planning (Mitterberger et al, 2006). Nevertheless, the patient must be counseled that hormonal replacement may still be necessary despite a seemingly successful cortex-sparing procedure. Life-threatening addisonian crisis can also occur despite close postoperative monitoring (Yip et al, 2004; Asari et al, 2006). Close long-term biochemical and radiographic follow-up is essential, whereas recurrence rates are poorly defined but appear to be significant (Yip et al, 2004; Asari et al, 2006).

Treatment of Malignant Pheochromocytoma. Currently therapy for metastatic pheochromocytoma is largely palliative. Surgical metastasectomy of resectable disease is the standard of care; however, little evidence exists to demonstrate that it prolongs patient survival or is more effective for symptomatic relief than medical treatment with α/β -blockade and α -methyl-*p*-tyrosine (Eisenhofer et al, 2004a; Lenders et al, 2005; Pacak, 2007). Local palliative tumor control using ablation techniques and embolization has also been described (Pacak et al, 2001a; Eisenhofer et al, 2004a).

Given the selective uptake of MIBG by pheochromocytoma cells, systemic treatment of metastatic disease with radioactive ^{131}I -MIBG may be instituted. Before initiation of therapy, MIBG uptake by tumor targets should be demonstrated with traditional MIBG imaging (Scholz et al, 2007). Symptomatic response is seen in up to 2 of 3 patients. Over 40% of patients exhibit a reduction in catecholamine levels. Tumor volume reduction occurs in approximately 30% of patients, but complete responses are seen in less than 5% (Loh et al, 1997; Scholz et al, 2007). High-dose therapy has been reported. Rose and colleagues (2003) described a multi-institutional study in which 12 patients were treated with ^{131}I -MIBG at 2 to 3.5 times its usual dose. Although toxicity was not trivial, 25% of patients ($n = 3$) exhibited a lasting complete response. Two of these patients had both bony and soft-tissue metastatic lesions. Given the significant toxicity, routine use of high-dose MIBG radiotherapy continues to be controversial (Lenders et al, 2005; Pacak et al, 2007; Scholz et al, 2007).

The best-studied chemotherapy regimen for malignant pheochromocytoma entails a combination of cyclophosphamide, vincristine, and dacarbazine (CVD). Although response rates can be significant (over 50% radiographic tumor response and nearly 75% biochemical response), they are typically short-lived (2 years) (Scholz et al, 2007; Huang et al, 2008). Chemotherapy is primarily used in patients in whom MIBG therapy has failed or in those whose tumors do not demonstrate MIBG uptake on initial MIBG imaging studies. Combination therapy with CVD and MIBG has been explored, but, to date, its risks and benefits remain poorly defined (Scholz et al, 2007).

Prognosis. After surgical resection, patients with pheochromocytoma typically do exceedingly well. Surgical mortality rates in the current era are less than 3% (Lenders et al, 2005). Hypertension

usually resolves after resection, but not in all cases (Plouin et al, 1997). Despite an excellent prognosis, the disease can recur many years after resection in up to 16% of patients, necessitating vigilant lifelong follow-up (Plouin et al, 1997; Goldstein et al, 1999; Eisenhofer et al, 2004a; Amar et al, 2005b). In one large series, patients with extra-adrenal disease (hazard ratio [HR] 11.2), hereditary pheochromocytomas (HR 3.4), right adrenal tumors (HR 3.1), bilateral tumors (HR 1.4), and larger tumors (HR 1.2 per centimeter of diameter) were more likely to recur. Some 50% of the recurrences were malignant (Amar et al, 2005b).

In some patients metastatic disease progresses rapidly, whereas others exhibit nonaggressive disease and can live in excess of 20 years (Huang et al, 2008). Bone metastases appear to carry the most benign prognosis (Pacak, 2007; Scholz et al, 2007). For all-comers, 5-year survival statistics vary but are believed to be approximately 50% (John et al, 1999; Lenders et al, 2005; Pacak et al, 2007; Scholz et al, 2007).

Summary. Pheochromocytoma is a rare catecholamine-producing tumor. Awareness of its potential presence and familiarity with its management are critical for every urologist. Misdiagnosis or mismanagement is often associated with dire consequences. Pheochromocytoma must be considered in every adrenal mass and referral to a tertiary care facility made if the physician is unfamiliar with the care of these complex patients.

KEY POINTS: PHEOCHROMOCYTOMA

- Nearly 25% of cases of pheochromocytoma that initially appear sporadic are later deemed hereditary on genetic testing.
- Testing for urinary or serum metanephrines (normetanephrine and metanephrine) represents the underpinning of modern biochemical testing for pheochromocytoma.
- Malignancy of pheochromocytoma can be defined only by presence of metastases. Pathologic appearance is unreliable. Long-term follow-up is paramount, because recurrences are reported even 15 years after the initial resection of a localized lesion.
- Familiarity with perioperative management of patients with pheochromocytoma is paramount.

Disorders of Decreased Adrenal Function

Overview and Epidemiology

Adrenal insufficiency, also known as *Addison disease*, is a condition whose management typically is beyond the scope of most urologic practices. Nonetheless, a working knowledge of the condition is essential for the urologic surgeon because the disease may result from either resection or pharmacologic inhibition of functioning adrenal tissues. Failure to consider and diagnose is potentially lethal and therefore warrants review. **Indeed, if the condition is not anticipated and appropriate proactive therapies are not instituted, addisonian crises following simultaneous or staged bilateral adrenalectomy can result in death (Asari et al, 2006).**

Adrenal insufficiency may be caused by primary adrenal failure or may occur secondary to extra-adrenal mechanisms. Its estimated prevalence is 39 to 60 per million (Oelkers, 1996).

Pathophysiology

In the Western world, the most frequent cause of primary adrenal insufficiency is autoimmune adrenalitis. This condition can occur in isolation or as a constellation of pathologies known as autoimmune polyendocrine syndrome (APS), wherein adrenal

insufficiency coexists with hypoparathyroidism, autoimmune thyroid disease, hypogonadism, diabetes, and other autoimmune conditions. Depending on the extent of endocrinologic involvement, APS is classified as either type 1 or the more common type 2 (Arlt and Allolio, 2003). In developing countries, as was true in the age of Thomas Addison, tuberculosis remains the major cause of adrenal failure (Løvås and Husebye, 2005). Other infectious causes, such as cytomegalovirus in the setting of human immunodeficiency virus (HIV) infection and rare fungal adrenalities, can also destroy the adrenal cortex. Bilateral adrenal hemorrhage or infiltrative diseases, such as amyloidosis, sarcoidosis, and hemochromatosis may also affect the function of the glands (Oelkers, 1996). Bilateral metastatic disease involving the adrenals, although classically described as a potential cause of adrenal insufficiency, is a very rare cause of clinically significant Addison disease (Lutz et al, 2000). In urologic practice, relevant clinical scenarios include simultaneous or staged surgical loss of bilateral adrenal tissue after treatment of adrenal or renal disease, and pharmacologic adrenalectomy with inhibitors of steroid hormone synthesis, such as ketoconazole, or new 17 α -hydroxylase (CYP17) inhibitors such as abiraterone (Arlt and Allolio, 2003). Although low postoperative day 1 cortisol levels (<3.4 μ g/dL) are not uncommon in patients after unilateral adrenalectomy (Mitchell et al, 2009), the clinical significance of such findings is unclear, and steroid replacement appears largely unnecessary for those without preoperative hypercortisolism (Shen et al, 2006). Nevertheless, a high index of suspicion for adrenal insufficiency must always remain in patients whose adrenal unit is removed.

Secondary adrenal insufficiency is caused by abnormalities in the pituitary gland or, less frequently, the hypothalamus. Tumors, radiation, autoimmune conditions, pituitary apoplexy (also known as *Sheehan syndrome* when it occurs peripartally), and trauma are less common causes of the condition. Rare congenital conditions marked by a metabolic error in the production of pituitary hormones, including ACTH, are rare causes of secondary Addison disease (Arlt and Allolio, 2003). Figure 65-21 summarizes the major causes of Addison disease. Important, given that aldosterone secretion by the adrenals does not depend on ACTH, the zona glomerulosa continues to function appropriately in patients with secondary adrenal insufficiency. **Mineralocorticoid deficiency is therefore present only in patients with primary Addison disease (White, 1994).**

Exogenous chronic administration of glucocorticoids accompanied by suppression of the HPA axis, resulting in secondary adrenal insufficiency, is particularly relevant to the surgeon (Krasner, 1999). Although overt adrenal crises caused by this clinical scenario are exceedingly rare, the possibility exists in surgical patients on chronic steroids (Axelrod, 2003). Postoperatively the urologist must also be cognizant of HPA axis failure in critically ill patients. This condition, recently termed *critical illness-related corticosteroid insufficiency*, is an important, albeit controversial, clinical entity (Marik et al, 2008; Marik, 2009).

Clinical Characteristics

Clinical signs and symptoms of Addison disease are usually nonspecific and constitutional in most outpatients, who may complain of profound fatigue and anorexia for many months before definitive diagnosis. Hyperpigmentation, a hallmark of primary adrenal insufficiency, results from high serum concentrations of ACTH in response to increased hypothalamic release of POMC-derived peptides that stimulate the melanocortin (MC1) receptor of the skin (Arlt and Allolio, 2003). Table 65-9 summarizes the clinical manifestations of adrenal insufficiency.

Acute adrenal insufficiency, or adrenal crisis, is a life-threatening condition often preceded by hypotension unresponsive to fluid resuscitation. Patients are easily and often misdiagnosed with an acute abdomen, whereas abdominal pain, nausea, vomiting, and fever frequently accompany hypovolemia in these individuals. Pediatric patients can exhibit hypoglycemic seizures (Arlt and Allolio, 2003; Bouillon, 2006).

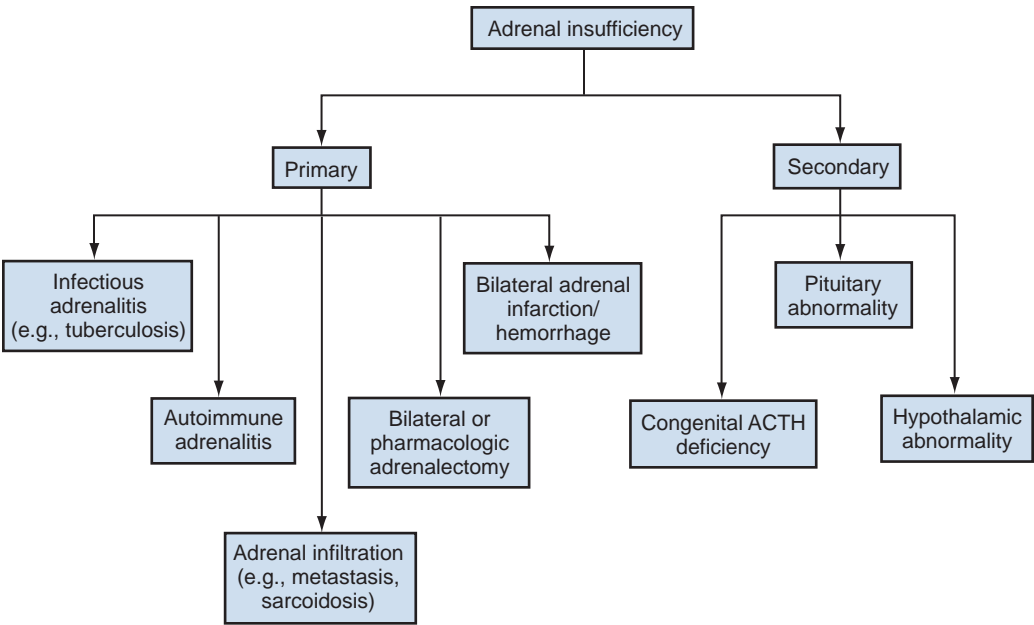

Figure 65-21. Causes of adrenal insufficiency. ACTH, adrenocorticotrophic hormone.

TABLE 65-9 Clinical Manifestations of Adrenal Insufficiency

	PATHOPHYSIOLOGY
SYMPTOMS	
Fatigue, lack of energy or stamina, reduced strength	Glucocorticoid deficiency, adrenal androgen deficiency
Anorexia, weight loss (in children, failure to thrive)	Glucocorticoid deficiency
Gastric pain, nausea, vomiting (more frequent in primary adrenal insufficiency)	Glucocorticoid deficiency, mineralocorticoid deficiency
Myalgia, joint pain	Glucocorticoid deficiency
Dizziness	Mineralocorticoid deficiency, glucocorticoid deficiency
Salt craving (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Dry and itchy skin (in women)	Adrenal androgen deficiency
Loss or impairment of libido (in women)	Adrenal androgen deficiency
SIGNS	
Skin hyperpigmentation (primary adrenal insufficiency only)	Excess of pro-opiomelanocortin–derived peptides
Alabaster-colored pale skin (secondary adrenal insufficiency only)	Deficiency of pro-opiomelanocortin–derived peptides
Fever	Glucocorticoid deficiency
Low blood pressure (systolic RR <100 mm Hg), postural hypotension (pronounced in primary adrenal insufficiency)	Mineralocorticoid deficiency, glucocorticoid deficiency
Raised serum creatinine (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Hyponatremia	Mineralocorticoid deficiency, glucocorticoid deficiency (leading to syndrome of inappropriate antidiuretic hormone secretion [SIADH])
Hyperkalemia (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Anemia, lymphocytosis, eosinophilia	Glucocorticoid deficiency
Increased thyroid-stimulating hormone (primary adrenal insufficiency only)	Glucocorticoid deficiency (or autoimmune thyroid failure)
Hypercalcemia (primary adrenal insufficiency only)	Glucocorticoid deficiency (mostly concurrent hyperthyroidism)
Hypoglycemia	Glucocorticoid deficiency
Loss of axillary or pubic hair (in women), absence of adrenarche or pubarche in children	Adrenal androgen deficiency

From Arlt W, Allolio B. Adrenal insufficiency. Lancet 2003;361(9372):1881–93.

TABLE 65-10 Perioperative Glucocorticoid Administration in Patients on Chronic Steroid Therapy

DEGREE OF SURGICAL STRESS	DEFINITION	GLUCOCORTICOID DOSE
Minor	Procedure under local anesthesia and less than 1 hour in duration (e.g., inguinal hernia repair)	Hydrocortisone 25 mg or equivalent.
Moderate	Procedure such as vascular surgery of a lower extremity or a total joint replacement	Hydrocortisone 50-75 mg or equivalent. This could be continuation of usual daily steroid dose (e.g., prednisone 10 mg/day) and hydrocortisone 50 mg intravenously during surgery.
Major	Procedure such as esophagogastrectomy or operation on cardiopulmonary bypass	Usual glucocorticoid (e.g., prednisone 40 mg or the parenteral equivalent within 2 hr before surgery) and hydrocortisone 50 mg intravenously q8h after the initial dose for the first 48-72 hr of the postoperative period.

Data from Salem M, Tainsh RE Jr, Bromberg J, et al. Perioperative glucocorticoid coverage. A reassessment 42 years after emergence of a problem. *Ann Surg* 1994;219(4):416-25; and Axelrod L. Perioperative management of patients treated with glucocorticoids. *Endocrinol Metab Clin North Am* 2003;32(2):367-83.

Adrenal insufficiency (an Addisonian state) after adrenalectomy in the setting of a normally functioning contralateral adrenal gland is unlikely, but possible. This is especially true for patients who are undergoing adrenalectomy for a cortisol-secreting lesion, because functionality of the contralateral gland can be suppressed (Shen et al, 2006; Tsagarakis et al, 2006; Mitchell et al, 2009; Phitayakorn and McHenry, 2012). Furthermore, patients with a history of contralateral partial or radical nephrectomy clearly represent a high-risk group. The integrity of the adrenal gland on the side of previous surgery may be compromised, or that gland may be altogether absent. Close examination of preoperative imaging and review of old operative and pathology reports for information regarding the status of the adrenal gland in the previous surgical field are paramount.

Diagnostic Tests

The diagnosis of primary adrenal insufficiency is primarily made on clinical grounds, with a high index of suspicion given a patient's history, examination findings, and laboratory evaluation. It is ultimately secured by measurements of morning serum cortisol and ACTH. Patients with primary Addison disease exhibit abnormal aldosterone and renin levels. Confirmatory testing involves assessing the adrenal response to ACTH stimulation in the form of the corticotropin test. The majority of patients with autoimmune adrenalitis demonstrate detectable levels of anti-21-hydroxylase antibodies (Oelkers et al, 1992; Arlt and Allolio, 2003).

The appropriate workup for secondary adrenal insufficiency often requires sophisticated probing of the HPA axis that goes beyond the scope of this text and requires endocrinologic expertise. In-depth reviews of the topic are available (Oelkers et al, 1992, 1996).

Treatment

The treatment of Addison disease involves adrenal hormonal replacement. Cortisol is replaced with hydrocortisone or with cortisone acetate. To mimic physiologic circadian glucocorticoid cycling, the majority (half or two thirds) of the daily dose is given in the morning, with the rest administered in one or two doses later in the day (Arlt and Allolio, 2003). Mineralocorticoid replacement is required only for patients with primary adrenal insufficiency and is achieved with fludrocortisone (Løvås and Husebye, 2005). Supplementation of adrenal androgens is advised by some experts, but is often limited to those who experience constitutional complaints despite adequate glucocorticoid and mineralocorticoid supplementation (Arlt and Allolio, 2003). Careful monitoring of patients on

hormone replacement for adrenal insufficiency is required and is often best left to experienced endocrine experts.

The necessity of perioperative stress-dose steroid administration continues to be controversial. Although continuing the patient's usual steroid dose is usually sufficient, given the negligible downside of perioperative steroid coverage and the potential catastrophic consequences of failure to prevent an adrenal crisis, surgeons continue to administer stress-dose steroids perioperatively. Tables 65-10 and 65-11 summarize contemporary recommendations (Salem et al, 1994; Krasner, 1999; Axelrod, 2003). Again, because aldosterone physiology is not altered in these patients, mineralocorticoid replacement is unnecessary (White, 1994).

Prognosis

The impact on life expectancy in cases of primary adrenal insufficiency has not been established; however, a significant impact on a patient's quality of life has been demonstrated (Løvås et al, 2002). Many patients complain of decreased energy, loss of libido, and psychologic maleffects (Arlt and Allolio, 2003). Secondary adrenal insufficiency from hypopituitary disease is an established cause of premature death (Tomlinson et al, 2001).

Summary

In urologic practice, adrenal insufficiency can result from simultaneous or staged surgical excision or pharmacologic ablation with steroid hormone synthesis blockade agents. Diagnosis requires a high index of suspicion. Patients having undergone ipsilateral partial or radical nephrectomy who are to undergo contralateral surgery constitute an at-risk population. Obtaining old operative or pathology reports and examining cross-sectional imaging for the presence or absence of adrenal tissue are essential in this setting. Postoperative adrenal insufficiency must be considered in patients on chronic glucocorticoid therapy or in the critically ill. There should be a low threshold to consult advanced endocrinologic expertise, given the complexity and the potentially grave consequences of the condition.

Disorders of Abnormal Adrenal Function

Congenital Adrenal Hyperplasia

CAH is a disorder that is characterized by low cortisol production caused by a metabolic enzymatic abnormality in the cholesterol-steroid biosynthesis pathway (see Fig. 65-3). The disorder is autosomal recessive and associated with a deficiency in the enzyme

TABLE 65-11 Relative Potency of Common Glucocorticoid Preparations

KEY POINTS: ADRENAL INSUFFICIENCY

- Mineralocorticoid deficiency is present only in patients with primary Addison disease (e.g., autoimmune adrenalitis, surgical absence of adrenal tissue). Abnormalities in the pituitary gland or, less frequently, the hypothalamus (e.g., in patients with suppressed ACTH secretion from chronic steroid use) do not result in suppression of aldosterone production.
- Any patient who has undergone ipsilateral partial or radical nephrectomy and is undergoing contralateral renal or adrenal surgery is at risk for a postoperative adrenal crisis. Obtaining old operative or pathology reports and examining cross-sectional imaging for the presence or absence of adrenal tissue are essential in this setting.

21-hydroxylase in over 95% of cases. In the absence of negative feedback, ACTH production by the pituitary is increased, resulting in hyperplasia of the adrenal cortex and overproduction of adrenal androgens (Merke and Bornstein, 2005). Diagnosis of the condition is most often established in childhood and is discussed in detail in Chapter 150. Patients with known CAH, as well as carriers of the CAH gene, appear to have a high propensity for developing benign adrenal cortical adenomas but are not at known increased risk for malignant adrenal lesions (Jaresch et al, 1992; Barzon et al, 2007). Patients with undiagnosed nonclassic 21-hydroxylase deficiency can develop adrenal neoplasms later in life (Ravichandran et al, 1996; Nigawara et al, 2008). Given the relatively low incidence, genetic screening of patients with adrenal incidentalomas has not demonstrated an increased incidence of undiagnosed CAH. Therefore screening of incidentaloma patients for CAH is not indicated (Kjellman et al, 1999; Barzon et al, 2003; Wagnierova et al, 2008).

Adrenal Lesions

Malignant

Adrenal Carcinoma

Overview and Epidemiology. ACC is a rare malignancy with an incidence of 0.5 to 2 per million (Aubert et al, 2002; Roman, 2006; Fassnacht et al, 2013). It has a bimodal age distribution that peaks in children in the first decade of life and adults in the fourth to fifth decades of life, although most patients with ACC are adults, with a slight female predominance of 1.5 to 2.1 (Roman, 2006). Several important differences exist between the pediatric and adult ACC populations, including symptoms at presentation, staging systems used, and prognosis. Compared with the adult population, children with ACC on presentation will more often have lower-stage functional tumors associated with improved survival (Liou and Kay, 2000).

The majority of ACCs are sporadic and unilateral; however, 2% to 6% of patients will have bilateral disease that may be associated with a hereditary disorder (Ng and Libertino, 2003). Although the cause of sporadic ACC remains unknown, several syndromes are associated with an increased incidence of ACC, including Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome, Lynch syndrome, Carney complex, MEN-1, and McCune-Albright syndrome (Else, 2012; Raymond et al, 2013). Although the underlying molecular defect of these syndromes has advanced our understanding of the tumorigenesis of ACC, significant improvements in treatment regimens and survival are yet to be realized. Currently, surgical resection remains the cornerstone of treatment and, when localized, offers the best chance of cure; however, multimodal therapy including systemic chemotherapy and radiation therapy are often required for locally advanced and metastatic disease. Over the last two decades there has been a lack of stage and size migration in patients diagnosed with ACC, despite “incidental screening” of the adrenal gland that has resulted from rising rates of cross-sectional imaging. Furthermore, ACC survival rates have also failed to improve (Kutikov et al, 2011a).

Pathophysiology. Two hereditary disorders, Li-Fraumeni syndrome and Beckwith-Wiedemann syndrome, have provided valuable insight into the tumorigenesis of sporadic ACC. Loss of TP53 function, as found in Li-Fraumeni syndrome, has been noted in 20% to 33% of sporadic ACC cases compared with 0% to 6% of adrenal cortical adenomas. Increased insulin-like growth factor (IGF) expression, as found in Beckwith-Wiedemann syndrome, has been noted in up to 90% of sporadic cases of ACC, compared with only 8.5% of adrenal cortical adenomas (Herbet et al, 2009). These findings suggest that loss of TP53 function and increased IGF expression represent late events in the tumorigenesis of sporadic ACC. Another common alteration noted in ACC is constitutive activation of the Wnt/ β -catenin pathway, which has been noted in 30% of cases (Lerario et al, 2014). Alterations of multiple other oncogenes and peptides have been associated with the ACC; however, the importance of how these alterations influence carcinogenesis, progression, and response to treatment of ACC remains unknown (Boulle et al, 1998; Kolomecki et al, 2001; Beuschlein et al, 2004; Sarkaria et al, 2004; Lehmann and Wrzesinski, 2012; Papotti et al, 2014).

Clinical Characteristics. Incidental detection of ACC has increased with the routine use of cross-sectional imaging; however, the majority of patients still have advanced disease and tumor-related symptoms on presentation. Figure 65-22 shows a CT image of a large right-sided ACC. Tumor-related symptoms of ACC can be secondary to local or systemic disease burden and/or hypersecretion of adrenal hormones, which has been noted in 50% to 79% of adult and 90% of pediatric ACCs (Roman, 2006). ACCs that are associated with the hypersecretion of adrenal hormones are characterized as being functional. However, the presence of a functional tumor does not always lead to clinical symptoms, as in the case of tumors that secrete high concentrations of steroid precursors. This

TABLE 65-12 Functional Breakdown of Adrenal Cortical Carcinomas

Nonfunctional	21%-50%
Functional	50%-79%
Cushing syndrome	33%-53%
Cushing syndrome plus virilization	20%-24%
Virilization alone	10%-20%
Feminization	6%-10%
Hyperaldosteronism	2.5%-5%

Figure 65-22. Axial cut in excretory phase of a computed tomography scan demonstrating a large right adrenal carcinoma. The right kidney is shifted anteriorly and medially. Similar-sized masses that arise from the kidney itself usually do not displace the renal unit. Important, even at this large size the adrenal carcinoma appears relatively homogeneous and well circumscribed—features deceptively camouflaging its deadly biologic potential. Surgical resection demonstrated a 25-cm, stage II (pT2N0M0), localized adrenocortical carcinoma. (Courtesy Dr. David Y. T. Chen, Fox Chase Cancer Center, Philadelphia.)

is especially relevant given the increasing sensitivity of assays used when evaluating serum hormone levels. Furthermore, it is common to have several hormones secreted by a single tumor, and it has been theorized that a tumor's functional status and hormones secreted may change throughout the tumor's development and growth (Phan, 2007).

The most common hormone secreted by ACC is cortisol, resulting in the clinical manifestations of Cushing syndrome (Table 65-12). Hypercortisolism in ACC is ACTH-independent, and the Cushing-associated virilization has been noted to be more pronounced compared with that resulting from functional adenomas. Recent data suggest that symptomatic hypercortisolemia is an independent prognosticator of survival in patients with resected localized ACC (Berruti et al, 2014). The observed increase in virilization may be the result of increased rates of cosecretion of 17-ketosteroids and DHEA in patients with ACC (Roman, 2006). Androgen-secreting tumors in women can lead to virilization, characterized by male-pattern baldness, hirsutism, and oligomenorrhea, which are typically related to elevated 17-ketosteroids. When virilization is present in the absence of elevated 17-ketosteroids, free testosterone hypersecretion from an adrenal or ovarian source should be considered. Feminization in men, characterized by testicular atrophy and gynecomastia, may result from peripheral conversion of androstenedione to estrogen and is highly suggestive of malignancy when present. Although hypersecretion of aldosterone is

TABLE 65-13 Functional Evaluation of Adrenal Tumors Suspected to Be Adrenocortical Carcinoma

TYPE OF ADRENAL HYPERSECRETION	FUNCTIONAL EVALUATION
Glucocorticoid excess	Low-dose dexamethasone suppression test or Late night salivary or 24-hour urine cortisol
Sexual steroids and steroid precursors	DHEA-S 17-OH-progesterone Androstenedione Testosterone 17 β -estradiol (only in men and postmenopausal women)
Catecholamine excess	Serum or urinary metanephrines
Mineralocorticoid excess	Aldosterone-to-renin ratio (only in patients with hypertension or hypokalemia)

DHEA-S, dehydroepiandrosterone sulfate.

Modified from Fassnacht M, Kenn W, Allolio B. Adrenal tumors: how to establish malignancy? *J Endocrinol Invest* 2004;27(4):387–99.

rarely associated with ACC, when present it is associated with profound hypertension and hypokalemia. Moreover, the symptoms of hypertension and hypokalemia are more likely secondary to other adrenal steroids produced by ACC, rather than the hypersecretion of aldosterone. Although considered functional, ACCs can result in high levels of steroid precursors, such as androstenedione and 17 α -hydroxyprogesterone, which may not cause any overt clinical symptoms (Fassnacht and Allolio, 2009). Nonfunctional ACCs may cause more generalized tumor-related symptoms, such as abdominal fullness, back pain, nausea, vomiting, or other constitutional symptoms.

Diagnostic Tests. Suspicion for ACCs is based on clinical symptoms or radiographic findings and warrants the complete extent of disease evaluation, given the implications of this malignancy. Evaluating the functional status of adrenal tumors suspicious for ACC is essential, not only for making the diagnosis of ACC but also for consideration of postoperative cortisol replacement and the potential use of tumor-secreted hormones as markers during postoperative surveillance. When considering the functional status of a tumor that raises suspicion for ACC, glucocorticoid, mineralocorticoid, catecholamine, sexual steroid, and steroid precursor excesses should be evaluated as outlined in Table 65-13.

The radiographic characteristics of an adrenal tumor provide valuable information regarding the lesion's malignant potential and may be obtained using several modalities including CT, MRI, and ¹⁸F-FDG PET imaging. On cross-sectional imaging, ACCs tend to be larger than benign adrenal tumors, with an average size of 10 to 12 cm on presentation. Indeed over 90% of ACCs are larger than 5 cm (Ng and Libertino, 2003; Fassnacht and Allolio, 2009). In incidentally detected adrenal tumors, size is a relative indicator of malignancy, with 4% to 5% of tumors smaller than 4 cm, 10% of tumors larger than 4 cm, and 25% of tumors larger than 6 cm found to be adrenal carcinomas (Sturgeon and Kebebew, 2004; Walz et al, 2005). Given the relationship between adrenal tumor size and malignancy, it is currently recommended that adrenal tumors larger than 4 to 6 cm be surgically excised (Scheingart et al, 2005). Although a complete metastatic evaluation should be completed for all adrenal tumors that raise suspicion for ACC, the presence of lymphadenopathy and local tumor extension into the

IVC and other adjacent organs are ominous indicators of locally advanced or distant metastatic disease. The most common sites of metastases in adrenal carcinoma are the lung and liver. Therefore metastatic evaluation at presentation should include cross-sectional imaging of the chest, abdomen, and pelvis. Evaluation for bone and central nervous system metastases need be performed only in patients with site-specific symptoms. **Common radiographic characteristics of adrenal carcinomas on CT imaging include the presence of irregular borders, irregular enhancement, calcifications, and necrotic areas with cystic degeneration. Mean attenuation on noncontrast CT scan in ACC is significantly higher (39 HU) compared with adenomas (8 HU). Classically, ACC does not exhibit brisk iodinated contrast washout characteristic of adenomas; however, these conclusions are based on limited data, and exceptions have been reported (Szolar et al, 2005; Roman, 2006; Simhan et al, 2012a) (see imaging section).**

MRI provides valuable information for evaluating adrenal tumors. ACCs appear isointense relative to the liver or spleen on T1-weighted images and demonstrate intermediate to increased intensity on T2-weighted images. On gadolinium-enhanced images, adrenal carcinomas demonstrate marked contrast uptake (Ilias et al, 2007). In cases of suspicion for venous tumor thrombus, MRI can be an essential tool in detecting the presence of a tumor clot and delineating its extent.

Available data suggest that ACC tends to be ^{18}F -FDG PET avid (Tenenbaum et al, 2004; Boland et al, 2011). However, given the established value of cross-sectional imaging in distinguishing benign from malignant disease, routine use of ^{18}F -FDG PET must be clinically calibrated.

In diagnosing ACCs, percutaneous needle biopsy is usually not performed before surgical excision owing to a clinically unacceptable risk of needle-tract seeding (Fassnacht et al, 2004; Schteingart et al, 2005). In cases of surgically resectable disease, the information obtained from biochemical and radiographic evaluation should be enough to justify extirpation. The primary indication for needle biopsy is in cases of unresectable, locally advanced, or metastatic disease, to confirm the diagnosis before systemic medical therapy.

Pathologic Evaluation. During the histologic evaluation of an adrenal tumor, tumor origin and malignancy are the two most important considerations. In cases in which tumor origin is questioned, SF1 expression can be evaluated, with positive staining suggesting adrenocortical origin (Fassnacht et al, 2013). Although the presence of distant metastasis and local invasion are clear indications of malignancy, the differentiation between benign and malignant neoplasms in organ-confined tumors can be pathologically challenging (Fig. 65-23). The Weiss criteria, developed in 1984, were established to distinguish benign from malignant adrenal tumors using nine pathologic features (Weiss, 1984). The classification system is based on tumor structure, cytology, and invasion (Box 65-4). The presence of three or more of the Weiss criteria is associated with malignancy, with a sensitivity of 100% and a specificity of 96% (Aubert et al, 2002). In cases of pediatric adrenal tumors, and in adult adrenal tumors that demonstrate oncocytic features, the Weiss criteria should be used with caution, and alternative diagnostic criteria are recommended (Lau and Weiss, 2009).

Staging. The American Joint Committee on Cancer (AJCC) staging of ACC is based on size of the primary tumor, degree of local invasion, and spread to regional lymph nodes or distant sites (Table 65-14). Stage I and II tumors are confined to the adrenal gland and are distinguished by a size cutoff of 5 cm. Stage III disease includes tumor extension into adjacent adipose tissue or the presence of regional lymph node involvement. Stage IV disease includes tumors invading adjacent organs and the presence of distant metastatic disease. The European Network for the Study of Adrenal Tumors (ENSAT) staging system of ACC is similar to the AJCC staging system; however, it differs in the grouping of patients with advanced disease. The ENSAT staging system maintains the tumor-node-metastasis (TNM) classifications used in the AJCC staging system (version 6); however, stage III disease includes patients with positive lymph nodes (N1), infiltration of surrounding tissues (T3 and T4),

and venous tumor thrombus, whereas stage IV disease is reserved for any tumor associated with distant metastatic disease (Fassnacht et al, 2009).

Management. Unfortunately, the majority of patients with ACCs have advanced disease on presentation (see Table 65-14), and those who do have localized disease are at a high risk of local recurrence and metastatic progression. For this reason, treatment of ACC often includes multimodal therapy directed by a team of surgeons, medical oncologists, endocrinologists, and radiation oncologists. Despite aggressive surgical resection, adrenal carcinoma is associated with a high rate (60% to 80%) of recurrent disease (Pommier and Brennan, 1992; Stojadinovic et al, 2002; Meyer et al, 2004). Thus, local and systemic adjuvant therapy is often administered, in spite of the lack of clear evidence demonstrating improved survival. Furthermore, given the low incidence of ACC, only one randomized trial has been completed evaluating the efficacy of current treatment regimens in patients with metastatic disease; thus the remaining treatment strategies are based on the collective experience of nonrandomized retrospective series.

Surgery. Complete surgical excision is essential in the management of ACC and offers the best chance of cure, control of symptoms secondary to hypersecretion of adrenal hormones, and other tumor-related symptoms in patients with localized disease. En bloc resection of surrounding organs involved with locally advanced disease should be performed whenever possible. Regional retroperitoneal lymph node dissection can provide additional disease control and staging information. Cases of venous tumor thrombus involving the IVC may require vascular bypass techniques, IVC replacement, and/or IVC interruption. Given the extent of resection frequently

BOX 65-4 Weiss Pathologic Criteria for Differentiating Benign and Malignant Adrenal Tumors

- High nuclear grade (Furman grade 3 to 4)
- High mitotic rate (greater than 5 mitoses per high-power field)
- Presence of atypical mitoses
- Character of cytoplasm (low percentage of clear cells)
- Diffuse architecture of tumor cells
- Presence of necrosis
- Invasion of venous structures
- Invasion of sinusoidal structures
- Invasion of tumor capsule

Sebo, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.)

required, open abdominal or retroperitoneal exploration is commonly performed. Smaller radiographically organ-confined disease can be approached laparoscopically, but the procedure should be performed with caution owing to the risk of tumor spillage (Kebebew et al, 2002; Gonzalez et al, 2005; Schlamp et al, 2007). In cases of metastatic adrenal carcinoma, cytoreductive removal of the primary tumor and debulking metastasectomy should be considered if more than 90% of the disease burden can be removed (Schteingart et al, 2005). Although debulking surgery may not improve survival, it may alleviate tumor-related side effects and facilitate additional therapies (Fassnacht et al, 2004). Local or distant disease recurrences after initial resection should be considered for surgical excision and have been associated with improved survival in retrospective series (Meyer et al, 2004; Dattice et al, 2012; Fassnacht et al, 2013). Locally recurrent disease and select metastatic lesions may be treated with ablative therapy using radiofrequency ablation or angioembolization, if surgical excision cannot be performed (Wood et al, 2003; Schteingart et al, 2005; Soga et al, 2009).

Follow-up should include CT examination of the chest, abdomen, and pelvis every 3 months for the first 2 years. The value of routine

PET imaging in disease surveillance has not been established. In patients with evidence of functional tumors, measurement of the initially elevated hormones postoperatively may help to reveal early disease recurrence despite negative radiographic studies. After a disease-free interval of 2 years, surveillance should continue, but the frequency of imaging may decrease (Schteingart et al, 2005; Fassnacht et al, 2013).

Radiation. Currently there is a limited role for radiation therapy in the treatment of primary ACCs; however, radiation therapy remains the treatment of choice in the management of bone and CNS metastasis (Schteingart et al, 2005). Adjuvant radiation has been noted to decrease local recurrence rates after complete tumor resection, with reported local recurrence rates of 14% and 79%, with and without adjuvant radiation therapy, respectively (Fassnacht et al, 2004; Polat et al, 2009). Unfortunately, a significant improvement in disease-free or overall survival was not observed. Patients believed to benefit the most from adjuvant radiation therapy are those without evidence of metastatic disease and positive or indeterminate surgical margins.

Medical Therapy. Mitotane is an oral synthetic derivative of the insecticide dichlorodiphenyltrichloroethane (DDT) and is the most

commonly used chemotherapeutic agent in the treatment of ACC. The agent has demonstrated clinical benefit in the adjuvant setting after surgical resection and in patients with metastatic disease (Phan, 2007). Three mechanisms of action of mitotane against ACC have been proposed: direct cytotoxicity of cells in the adrenal cortex, oxidative damage through the production of free radicals, and/or inhibition of enzymes involved with steroid synthesis (Fassnacht and Allolio, 2009). Owing to the adrenolytic effect of mitotane, steroid replacement is typically necessary during therapy. In addition to adrenal insufficiency, common side effects include gastrointestinal upset, lethargy, depression, feminization in males, rash, elevation of hepatic enzymes, elevation of hormone-binding globulins, hypothyroidism, dyslipidemia, and thrombocytopenia. Given its significant adverse effect profile and its marginal therapeutic benefit, administration must be closely monitored and dosage titrated according to patient tolerability and serum levels (Fassnacht and Allolio, 2009).

The efficacy of adjuvant mitotane following surgical resection has been evaluated by several small retrospective series with varying results. A more contemporary retrospective series by Terzolo and colleagues (2007) evaluated the impact of adjuvant mitotane on recurrence-free survival and overall survival in 177 patients with ACC. A significant increase in recurrence-free survival and overall survival was noted in patients receiving mitotane compared with controls, after multivariate adjustments. In addition, treatment-related toxicity appeared acceptably low. Currently, significant questions remain regarding the routine use of adjuvant mitotane after surgical resection, including which patients will derive the greatest benefit from adjuvant therapy, and the optimal dosage and duration of adjuvant mitotane therapy (Terzolo et al, 2007, 2009; Else et al, 2014).

In patients who are not candidates for complete tumor debulking, surgery should not be performed because it will delay systemic therapy. Currently, mitotane remains the primary systemic therapy, either as a single agent or in combination with other cytotoxic drugs for ACCs. As a single agent, overall responses to mitotane range from 14% to 36%, with few studies demonstrating a significant survival benefit (Roman, 2006; Phan, 2007). A series by Khan and colleagues (2000), investigating the combination of mitotane and streptozotocin, noted a response rate of 36%. In a report by Berruti and colleagues (2005), a response rate of 49% was noted with the combination of mitotane, etoposide, doxorubicin, and cisplatin. The First International Randomized Trial in Locally Advanced and Metastatic Adrenocortical Carcinoma Treatment (FIRM-ACT) randomized patients to receive mitotane in combination with streptozotocin or etoposide, doxorubicin, and cisplatin (M-EDP) (Fassnacht et al, 2012). Overall survival was similar between groups; however, patients receiving M-EDP were noted to have improved objective response rates and progression-free survival. Based on the results of this trial, M-EDP is now being considered the first-line regimen of choice in patients requiring systemic therapy. With the known limited success of first-line therapy for advanced disease, salvage therapy is often required. Multiple ongoing trials are investigating targeted therapies and other agents in patients in whom the disease progresses after first-line systemic therapy (Roman, 2006; Lebastchi et al, 2012; Fassnacht et al, 2013).

Control of symptoms secondary to the hypersecretion of hormones is often necessary in patients with metastatic disease. Although mitotane has adrenolytic activity, given its delayed onset of action and associated toxicity, other agents are often necessary to help control symptoms of hormone hypersecretion. Adrenostatic drugs such as ketoconazole, metyrapone, aminoglutethimide, and etomidate have been used to decrease circulating levels of cortisol in symptomatic patients (Fassnacht et al, 2004).

Prognosis. Overall 5-year survival in ACCs is poor, ranging from 20% to 47% (Roman, 2006; Fassnacht and Allolio, 2009). The observed poor prognosis associated with ACC reflects the advanced stage frequently noted at presentation, the high rate of recurrent disease in patients with localized disease, and the limited efficacy of current systemic treatment regimens. Administrative datasets reveal that tumor size at resection in patients with localized disease

fails to show a strong relationship with overall survival (Canter et al, 2013). Five-year survival based on tumor stage is presented in Table 65-14. In addition to advanced stage, several clinicopathologic features have been associated with decreased survival, including tumor size greater than 12 cm, age, high mitotic rate, tumor necrosis, atypical mitotic figures, and high Ki-67 staining (Fassnacht and Allolio, 2009; Ayala-Ramirez et al, 2013). The impact of a tumor's functional status on outcome has been widely debated and remains controversial (Luton et al, 1990; Favia et al, 2001; Chen et al, 2004; Vaughan, 2004).

Pediatric Adrenocortical Carcinoma. The presentation, staging, and prognosis of pediatric ACC differ from those in adults (Liou and Kay, 2000). More than 90% of ACCs in children are functional at the time of presentation, with virilization being the most common clinical manifestation, occurring in 55% to 70% of patients. Unlike in adults, the female-to-male ratio is equal in children younger than age 12; it sharply increases to 6:1 in children aged 13 to 20. Genetic syndromes should be considered in pediatric cases of adrenal carcinoma, particularly Li-Fraumeni syndrome, because a high rate of TP53 mutations has been noted in prior series. The staging system in pediatric patients defines stage I and II tumors as being completely excised with negative margins and with a tumor weight of greater than 200 g differentiating stage I and II disease. Stage III disease is defined by the presence of microscopic or macroscopic residual disease after surgical resection or inoperable tumors; stage IV disease is defined by the presence of hematogenous metastasis. The overall 5-year survival rate is 54.2%, with several clinicopathologic features associated with diminished survival, including tumors weighing more than 400 g, tumor size greater than 10.5 cm, necrosis, frequent and atypical mitotic bodies, and presentation after 5 years of age (Michalkiewicz et al, 2004; McAteer et al, 2013).

Summary. ACC is a rare malignancy requiring multispecialty care. Given the aggressive natural history of the disease, ACC must be considered in the differential diagnosis in all patients with an adrenal tumor, particularly if larger than 6 cm. Evaluation of tumor functional status is critical for preoperative planning and supportive care, even in asymptomatic patients. Complete surgical resection of the primary tumor and any associated metastatic lesions should be performed whenever possible. Adjuvant therapy or enrollment into a clinical trial should be considered in most patients, given the high rate of local recurrence and metastatic progression despite complete surgical resection. Systemic therapy with mitotane therapy alone, or in combination with other cytotoxic agents, is recommended as first-line therapy in patients with metastatic ACC. Unfortunately, the prognosis for patients with ACC is poor, and improved therapeutic regimens are needed to improve outcomes.

KEY POINTS: ADRENAL CORTICAL CARCINOMA

- Increasing adrenal tumor size is significantly associated with an increased risk of malignancy.
- The majority of ACCs will be functional at the time of presentation.
- Multimodal treatment, surgical resection, radiation therapy, and systemic chemotherapy are often necessary for patients with ACC.

Neuroblastoma. Neuroblastoma, a malignancy derived from the cells of the neural crest, which give rise to the adrenal medulla and sympathetic ganglia, is the most common solid extracranial tumor of childhood. Chapter 155 is dedicated to the clinical and pathologic features of this entity (Park et al, 2008).

Metastases

Overview and Epidemiology. The adrenal glands are a common site of metastases. Large autopsy series have demonstrated that over 25% of patients with melanoma and lung carcinoma have metastases to their adrenals (Bullock and Hirst, 1953). RCC, breast cancer, medullary thyroid carcinoma, contralateral ACC, gastrointestinal

malignancies, prostate adenocarcinoma, cervical cancer, basal cell carcinoma, pancreatic tumors, cholangiocarcinoma, urothelial carcinoma, squamous cell carcinoma, seminoma, thymoma, chronic myelogenous leukemia, and other malignancies can all exhibit metastatic deposits within the adrenals (Bullock and Hirst, 1953; Lenert et al, 2001). Indeed, diagnostic challenges arise when an adrenal incidentaloma is discovered in patients with a known malignancy. It has been estimated that in patients with a history of a previous malignancy, over 50% of newly discovered adrenal lesions are metastatic (Lenert et al, 2001; Frilling et al, 2004). Current imaging modalities supplemented by adrenal biopsy, when necessary, can frequently differentiate metastases from a primary adrenal tumor.

RCC can involve the adrenal by direct invasion or systemic metastases (Lau et al, 2003; Antonelli et al, 2006). O'Malley and colleagues (2009) provide a recent review of these data as they relate to the need for adrenalectomy during surgery for RCC. Management of solitary metastases to the adrenal from other malignancies often falls within the purview of the practicing urologist. Indeed, for some malignancies, specifically melanoma and non-small cell lung carcinoma, a survival benefit has been suggested in patients who undergo resection of an isolated adrenal metastasis (Mercier et al, 2005; Collinson et al, 2008; Mittendorf et al, 2008; Tanvetyanov et al, 2008).

Pathophysiology and Clinical Characteristics. Remarkably few patients with metastatic disease to the adrenal gland exhibit evidence of adrenal insufficiency. Indeed, although an Addisonian state secondary to metastatic carcinoma was described by Addison in his original series, the scenario is exceedingly rare (Addison, 1855; Lutz et al, 2000). Some reports suggest that bulky (>4 cm) bilateral disease is necessary to produce biochemical evidence of adrenal insufficiency (Lutz et al, 2000). The statement that adrenal insufficiency exists in 20% of patients with metastatic RCC is, at times, quoted in the urologic literature. This supposition is based on an isolated report from the 1980s (involving a cohort of 15 patients) that, to our knowledge, has been published only in abstract form (Schorr et al, 1986). Indeed, patients with advanced malignancy may exhibit symptoms of an Addisonian state (i.e., nausea, vomiting, fatigue, weight loss, and so on) in the absence of biochemical evidence of adrenal insufficiency (Lutz et al, 2000).

Diagnostic Tests. Radiographically metastatic lesions, similar to benign adenomas, appear well circumscribed and homogeneous and most often lack areas of macroscopic necrosis (Boland et al, 2008). Nevertheless, metastatic disease often can be differentiated from the typical adrenal adenoma based on its lack of substantial lipid content. As is discussed in the imaging section of this chapter, metastatic lesions exhibit greater than 10 HU in attenuation on noncontrast imaging and fail to demonstrate significant contrast loss on adrenal washout studies (Fig. 65-24) (Boland et al, 2008). Recent literature, however, suggests that without characteristics of RCC and hepatocellular carcinoma metastases can mimic those of lipid-poor adenomas. Accordingly, when metastases from these primary tumor sites are suspected, adrenal nodule growth kinetics become critical in formulating clinical decision (Choi et al, 2013). Furthermore, adrenal biopsy can be helpful with newly found adrenal lesions in the setting of a known history of malignancy when imaging is equivocal. Unlike with metastases to the kidney, which are frequently associated with widespread metastatic disease, metastases to the adrenals can occur early and may be the sole focus of radiographically identifiable disease, making therapeutic resection feasible. (See the section on adrenal biopsy for more details.)

Nonetheless, a standard metabolic workup is warranted to rule out functionality of any new adrenal lesion (Lenert et al, 2001). Indeed, some small series report no difference in the incidence of metabolically active tumors, when patients with and without a history of extra-adrenal malignancy are compared (Tsvetov et al, 2007). It is important to note that reports of pigmented pheochromocytomas being mislabeled as metastatic melanoma exist in the literature (Lenert et al, 2001).

Treatment and Prognosis. Resection of metastases to the contralateral or ipsilateral adrenal gland from RCC is advocated in the

Figure 65-24. Unenhanced computed tomography scan of a patient with a left adrenal metastasis from right-sided renal cell carcinoma (RCC) that had been resected several years earlier. At presentation, unenhanced imaging revealed a lesion with an attenuation of greater than 10 Hounsfield units (HU), indicating that the adrenal mass was not a lipid-rich adenoma. Recent data reveal that RCC metastases may exhibit washout characteristics similar to lipid-poor adenomas. Metabolic evaluation ruled out pheochromocytoma. Laparoscopic adrenalectomy confirmed metastatic RCC.

context of a cytoreductive approach for a select group of patients. Nevertheless, benefits to adrenal metastasectomy are as yet unproven in a prospective fashion. Moreover, the role of resection may change with antiangiogenic targeted therapies (Lau et al, 2003; Antonelli et al, 2006; O'Malley et al, 2009). Treatment of metastatic disease of the adrenals in patients with nonurologic malignancies requires a multidisciplinary approach. The urologist must work closely with the patient's primary medical oncologist regarding the surgical and biologic prudence of resection. Lenert and colleagues (2001) have reported their experience with adrenalectomy for solitary adrenal metastases from over 20 separate primary malignancies. Currently, the best data regarding adrenal metastasectomy exist for patients with non-small cell lung carcinoma and melanoma (Branum et al, 1991; Mittendorf et al, 2008).

In patients with non-small cell lung cancer, adrenal metastases are most frequently encountered in the setting of systemic disease. An isolated adrenal metastasis is rare and may be the result of nonhematogenous lymphatic spread (Tanvetyanov et al, 2008). Surgical resection of solitary adrenal metastases has been associated with 5-year overall survival rates of over 25% (Mercier et al, 2005; Strong et al, 2007; Tanvetyanov et al, 2008). Although the prognosis after resection in patients with metachronous metastasis and longer disease-free intervals is thought to be better than in patients found to have an isolated adrenal metastasis at the time of their initial diagnosis, a meta-analysis from 2008 demonstrated that the 5-year overall survival is equivalent in both groups (Tanvetyanov et al, 2008). In patients with metastatic melanoma, adrenalectomy has been reported to be associated with long-term survival and even rare regression of distant disease (Branum et al, 1991; Collinson et al, 2008). Nevertheless, data are limited to retrospective reports describing highly selected patient populations (Mittendorf et al, 2008).

Summary. Metastatic disease to the adrenal is common and must be suspected when patients with a history of malignancy are found to have adrenal incidentaloma. Radiographic and functional studies are essential and often secure the diagnosis. Percutaneous biopsy is safe, but its success depends on the size and location of the lesion and the technical aspects of the procedure. Adrenalectomy for

patients with solitary adrenal metastasis is a viable option for a select group of individuals.

KEY POINTS: ADRENAL METASTASES

- Metastatic disease to the adrenals is common, yet it appears that bilateral and bulky disease (>4 cm) is necessary to produce biochemical evidence of adrenal insufficiency.
- More than 50% of newly discovered adrenal lesions in patients with a history of previous malignancy represent metastatic disease; nevertheless, metabolic workup in these patients is recommended.

Malignant Pheochromocytoma. Malignant pheochromocytomas are discussed in the section on pheochromocytoma under Disorders of Increased Adrenal Function.

Benign

Adenoma

Overview and Epidemiology. Adenomas are the most common neoplasms arising from the adrenal gland and are most often associated with the cortex. These lesions are found in approximately 6% of patients at autopsy (Kloos et al, 1995). Clinically, adrenal adenomas are most often incidentally discovered on cross-sectional imaging obtained for other indications and are thus termed *incidentalomas*. More than 85% of adrenal neoplasms incidentally discovered on imaging are ultimately clinically proven to be adenomas (Young, 2000, 2007b). The incidence of adenomas rises with age, as inferred from the observation that incidentalomas are found in less than 0.5% of individuals in their 20s and in up to 7% of those aged 70 years or older (Young, 2000). Similar trends are observed in historical autopsy series (Commons and Callaway, 1948; Russell et al, 1972). Despite benign behavior, a small percentage of adrenal adenomas can exhibit metabolic activity and therefore can represent “surgical” lesions. The essential evaluation of the small adrenal mass requires differentiating the nonfunctional benign adenoma from functional or malignant lesions.

Pathophysiology and Clinical Characteristics. Adenomas possess a yellowish color on gross pathologic examination owing to the presence of abundant lipid. Histologically, they may be difficult to distinguish from adrenal adenocarcinomas. As discussed earlier (see Box 65-4), pathologists use a set of criteria proposed by Weiss along with modern immunohistochemical methods to differentiate the two clinical entities (Weiss, 1984; Aubert et al, 2002; Sasano et al, 2006).

Adrenal adenomas are by definition benign, and the vast majority is metabolically silent. An analysis of the 13 largest series of incidental adrenal masses (N = 2005) reveals that nearly 90% (n = 1779) of these lesions were clinically benign adenomas. Of these, only 127 lesions (7.1% of adenomas) exhibited metabolic activity, 107 (6% of adenomas) hypersecreted glucocorticoids, and 20 (1.1% of adenomas) were functioning hyperaldosteronomas. The overwhelming majority (93%) of adenomas displayed no evidence of metabolic activity (Young, 2000, 2007b). Hypersecretion of sex steroids by benign adrenal adenomas is exceedingly rare but has been reported. It is interesting to note that these rare lesions may secrete testosterone and possess Reinke crystals, normally identified in testosterone-producing Leydig cells of the testes (Ryan et al, 1995). The implications of glucocorticoid and mineralocorticoid hypersecretion by adrenal adenomas are discussed in detail in the sections on Cushing syndrome and primary aldosteronism, respectively. Finally, it has been hypothesized that nonfunctional adrenal adenomas may be associated with physiologic derangements, such as insulin resistance and left ventricular dysfunction; however, such reports are isolated to small single-institution series and await confirmation (Midorikawa et al, 2001; Ermetici et al, 2008).

The growth kinetics of adrenal adenomas is reviewed later (see discussion on incidentalomas). In brief, an analysis of 18 reported series following over 850 patients with adrenal incidentalomas revealed that the vast majority of these benign masses remained stable in size; however, approximately 9% of lesions increased by more than 1 cm in diameter over a mean follow-up of 3 years (Barzon et al, 2003). The size and growth of adrenal lesions are discussed in detail in a later section of this chapter.

The current literature suggests that adenomas that are initially metabolically inert are unlikely to gain function. An analysis of 18 published series reporting more than 1100 incidental adrenal masses (not all of them adenomas) revealed that only 1.7% became metabolically active in follow-up, including 0.65% that developed subclinical Cushing syndrome, 0.3% with subsequent overt Cushing syndrome, and 0.05% that were identified as becoming functional secretors of catecholamines. No lesion produced new-onset hyperaldosteronism during endocrinologic reevaluation (Barzon et al, 2003).

Diagnostic Tests. The evaluation of incidental adrenal lesions, the primary way that adenomas come to clinical attention, is discussed in detail elsewhere in this chapter. In this section, we review the salient points of the clinical workup as it relates to adenomas. The goal in evaluating any adrenal lesion is twofold: (1) rule out the possibility of malignancy and (2) document metabolic inactivity of the lesion in question.

Noncontrast CT scan is arguably the most valuable imaging study for the diagnosis of an adrenal adenoma. CT affords accurate measurements of a lesion’s density, uniformity, and size. The vast majority of adrenal adenomas are smooth-bordered, homogeneous tumors that are less than 4 cm in diameter (Grumbach et al, 2003). High intracytoplasmic lipid content is unique to adenomas, and this attribute affords accurate differentiation of adenomas from other adrenal lesions on cross-sectional imaging. According to an NIH 2002 consensus panel, an adrenal mass with an attenuation of less than 10 HU on unenhanced CT is “strongly suggest[ive of] a benign adrenal adenoma” (Grumbach et al, 2003). Indeed, a large contemporary series of resected adrenal masses from the Cleveland Clinic demonstrated 100% specificity when the threshold of less than 10 HU was applied to lesions in this cohort (Hamrahian et al, 2005). The 100% specificity for adenoma was retained if only masses equal to 4 cm were considered and the threshold was raised to 20 HU (Hamrahian et al, 2005). Nevertheless, not all adenomas have sufficient intracytoplasmic fat content to result in attenuation below 10 HU on noncontrast CT. Approximately 30% of adrenal adenomas register a density greater than 10 HU on unenhanced CT (Korobkin et al, 1998; Pena et al, 2000; Szolar et al, 2005). However, even in these cases a diagnosis of adenoma is still possible with use of the “washout” technique, whereby loss of attenuation of the lesion is noted on delayed contrast-enhanced CT imaging. Lesions that wash out more than 40% to 60% of gained enhancement can be identified as adenomas with extremely high specificity (Fig. 65-25) (Korobkin et al, 1998; Pena et al, 2000; Szolar et al, 2005; Heinz-Peer et al, 2007). The urologist must be aware, however, that RCC and hepatocellular carcinoma metastases may exhibit washout characteristics similar to lipid-poor adenomas (Choi et al, 2013). MRI also can be used to successfully characterize adrenal adenomas. Chemical shift ratios relating to in- and out-of-phase imaging substitute for CT attenuation values. Although, in general, adenomas do not exhibit significant FDG uptake on PET imaging, exceptions exist. Accordingly, increased standardized uptake values (SUVs) of an adrenal lesion with otherwise benign imaging characteristics must be interpreted in the context of each clinical scenario, especially when pretest probability of malignancy is low (Boland et al, 2011; Canter et al, 2011). Refer to the imaging section for further details on imaging of adrenal adenomas (Outwater et al, 1996; Hussain and Korobkin, 2004; Heinz-Peer et al, 2007).

Classically, incidentalomas are evaluated for excess cortisol and catecholamine secretion. In patients with a history of hypertension, hyperaldosteronemia also should be ruled out (Grumbach et al, 2003). Adenomas themselves have the potential to secrete only cortisol or aldosterone; therefore, strictly speaking, if

Figure 65-25. Axial cut of an unenhanced computed tomography scan in a patient with a 3.5-cm, right, lipid-rich adrenal adenoma, demonstrating an attenuation of less than 10 Hounsfield units (HU).

a diagnosis of adenoma is unequivocal on imaging, metabolic workup for pheochromocytoma risks false-positive results given the imperfect specificity of testing. Nevertheless, current recommendations suggest serum or urine metanephrine testing for all adrenal lesions (Grumbach et al, 2003; Young, 2007b). Indeed, pheochromocytomas that mimic adenomas on imaging have been reported, validating the recommendation for metanephrine testing of all adrenal lesions (Blake et al, 2003). Despite the 2002 NIH consensus statement that all adrenal lesions larger than 1 cm should undergo a metabolic evaluation, current literature suggests that more than 80% of adrenal masses are not appropriately radiographically or functionally evaluated in routine clinical practice (Eldeiry and Garber, 2008).

Treatment. Adenomas that are metabolically active should undergo resection in acceptable surgical candidates. In patients with nonfunctional adenomas, the size of lesion and its growth characteristics dictate management. Notwithstanding benign imaging features, experts suggest that resection of all adrenal masses larger than 6 cm is prudent, given that adenomas of this size are rare and the risk of malignancy is substantial. The one exception to this may be a definitively diagnosed adrenal myelolipoma (Grumbach et al, 2003). Others argue that a cutoff of 4 cm should be used (Young, 2007b). Lesions that are not resected should undergo at least initial radiographic follow-up to ascertain growth kinetics. Reimaging at 6, 12, and, potentially, 24 months has been recommended to verify benign clinical biology and indolent growth (Grumbach et al, 2003; Young, 2007b). Suspicious and unusual tumors may necessitate imaging at earlier or more frequent intervals or removal (Young, 2007b). As already discussed, although reports in the literature vary, on average approximately 2% of incidentalomas that are initially metabolically silent result in superphysiologic hormone production during follow-up (Barzon et al, 2003). Despite this low rate of “metabolic transformation,” the most recent consensus statement by a panel of NIH-convened experts suggests that annual metabolic hormonal screening for the first 3 to 4 years after diagnosis is prudent, especially for masses that are equal to 3 cm in diameter (Grumbach et al, 2003). Nevertheless, given lack of strong data supporting this recommendation, the need for metabolic reevaluation of adrenal adenomas in patients who show no clinical signs of hormonal hypersecretion remains controversial (Barry et al, 1998; Bulow et al, 2006; Young, 2007b).

Prognosis. Normalization of serum cortisol levels after resection of adenoma likely reduces but does not eradicate heightened cardiovascular risk in patients with Cushing syndrome (Swearingen et al, 1999; Pivonello et al, 2005). For patients with hyperaldosteronism,

serum aldosterone and blood pressure often return to normal within 3 months of adrenalectomy (Young, 2007a), although those with baseline essential hypertension may remain medication-dependent. In general, patients with nonfunctional adrenal adenomas appear to be unaffected by their diagnoses. A large surveillance series from the Mayo Clinic (N = 231) demonstrated that no patients died as a result of a condition that could be ascribed to adrenal pathology after a mean follow-up of 7 years (Barry et al, 1998).

Summary. Adrenal adenomas account for more than 80% of incidental adrenal neoplasms. Because of their abundance of intracellular lipid, these lesions possess characteristic imaging features. More than 90% of these lesions are metabolically silent and require no treatment; however, all should be subjected to an initial metabolic evaluation. Lesions larger than 4 to 6 cm and metabolically active lesions should be resected in patients who are appropriate surgical candidates.

KEY POINTS: ADENOMA

- Incidence of adrenal adenoma rises with age.
- Approximately 7% of adrenal adenomas exhibit metabolic hyperactivity. Those that are metabolically inert at diagnosis only rarely (<2%) gain function on follow-up.
- Radiographic diagnosis of adrenal adenoma pivots on its high lipid content.

Oncocytoma

Overview and Epidemiology. Oncocytomas are familiar to the urologist, given their relatively common renal origin (Chang and Harawi, 1992). Oncocytic tumors can also arise from the salivary gland and the endocrine organs. Adrenal lesions are exceedingly rare (Bisceglia et al, 2004), with approximately 50 cases having been reported in the literature (Juliano et al, 2008).

Pathophysiology and Clinical Characteristics. Like oncocytic tumors in other organs, oncocytic adrenal lesions are characterized histologically by mitochondria-rich, large, eosinophilic cells with abundant granulations (Chang and Harawi, 1992). The pathogenesis of oncocytic neoplasias is poorly understood (Chang and Harawi, 1992). Females have been reported to be affected 2.5 times more frequently than males, and left-sided lesions outnumber those in the right adrenal 3.5 to 1. Tumors can grow up to 20 cm, and at least two cases have been reported in pregnancy (Bisceglia et al, 2004; Juliano et al, 2008). Most lesions that are documented in the literature are metabolically inactive; however, some oncocytic adrenal neoplasms (n = 6, or approximately 10% of all cases reported) hypersecrete sex steroids, cytokines, and/or cortisol (Akatsu et al, 2008; Juliano et al, 2008; Lee et al, 2008). Classically, these lesions have been considered benign (Vaughan and Blumenfeld, 2007); however, over 30% of reported lesions have been classified as malignant, with an additional 23% having been designated as pathologically indeterminate (Juliano et al, 2008). These reports include a lesion that locally invaded the IVC (El-Naggar et al, 1991).

Diagnostic Tests and Treatment. Because the diagnosis of adrenal oncocytic tumor is nearly always made on surgical resection, the evaluation and treatment of oncocytic lesions follow the same strategy as that of other adrenal masses. On imaging, adrenal oncocytic lesions are not reported to regularly possess the central stellate scar that may characterize such cases in the kidney (Lee et al, 2006). The optimal treatment for malignant oncocytic lesions is unknown; however, in at least one report, metastasectomy and radiation treatment for local recurrence may play a role (Juliano et al, 2008).

Prognosis. Given the emerging appreciation for the heterogeneity of the biologic behavior of adrenal oncocytic lesions, the prognosis of patients with these lesions is uncertain but leans toward the more benign. Some reports suggest that even patients with widely metastatic disease can exhibit slow disease progression with long-term survival (Juliano et al, 2008).

Summary. Adrenal oncocytic tumors are extremely rare neoplasms. Despite predominantly benign classical descriptions, a proportion of lesions can exhibit malignant potential.

KEY POINT: ONCOCYTOMA

- Unlike renal oncocytomas, a large proportion of adrenal lesions are malignant.

Myelolipoma

Overview and Epidemiology. Myelolipomas are rare, benign, metabolically silent lesions that arise primarily from the adrenal gland and arise in patients in all age groups (Han et al, 1997). Based on historical autopsy series, the incidence of these lesions is estimated at less than 0.1% percent (Olsson et al, 1973; Bishop et al, 2006). Some reports suggest that 15% of all myelolipomas are extra-adrenal, with up to half of these arising in the presacral area. Thoracic, retroperitoneal, pelvic, renal, hepatic, and gastric lesions have all been reported (Patel et al, 2006).

Pathophysiology. Myelolipomas appear to result from clonal stem cell proliferation and are composed of an unusual mixture of mature adipose tissue and relatively normal trilineage hematopoietic elements (Bishop et al, 2006). Overabundance of megakaryocytes has been reported. Unlike in normal bone marrow, cellularity within myelolipomas varies greatly and does not decrease with increasing patient age. These lesions do not appear to contribute hematopoietic cells to the circulation, which may be a result of irregularities in stromal support and a lack of appropriate microvasculature. Specifically, normal capillary venous sinuses that are critical to functional bone marrow are nearly always absent in myelolipomas (Bishop et al, 2006).

Experimentally, myelolipoma generation has been induced in the adrenals of rats after injection with necrotic tumor tissues and ACTH (Seyle and Stone, 1950). This observation has resulted in the hypothesis that myelolipomas are a result of an adrenal stress response. Additional theories exist, and the cause of these unusual tumors remains unknown (Han et al, 1997; Bishop et al, 2006).

Clinical Characteristics. Men and women are affected with relatively equal frequency. The tumor does not appear to have a predilection for either the right or left adrenal. Bilateral lesions have been reported (Bishoff et al, 1997; Han et al, 1997; Russell et al, 2000). Tumors vary greatly in size and can grow in excess of 10 cm. In a single institutional series of 21 lesions, the average tumor size was

5.1 cm (Han et al, 1997). As with most retroperitoneal tumors, these lesions are usually asymptomatic, although some patients do seek medical attention with abdominal or flank pain (Han et al, 1997). Spontaneous rupture of myelolipomas has been reported; however, this event is rare. Indeed, the mean tumor size of myelolipomas that have ruptured exceeds 10 cm (range 6.3 to 14.7 cm) (Russell et al, 2000).

Classically, myelolipomas are metabolically nonfunctional lesions. Nevertheless, the literature contains over two dozen cases in which myelolipomas are associated with adrenal metabolic hyperactivity. The most common abnormality appears to be hypercortisolemia (Hisamatsu et al, 2004). In the majority of patients, the myelolipoma is not the source of excess hormone production but coexists with a hyperfunctional adrenal adenoma. Indeed, some have suggested that these cases substantiate the early animal model wherein rat adrenal hyperstimulation with pituitary extract resulted in myelolipoma formation (Seyle and Stone, 1950; Hisamatsu et al, 2004).

Diagnostic Tests. In the majority of cases, diagnosis of myelolipoma can be made accurately on cross-sectional imaging. CT reveals a well-circumscribed adrenal lesion with varying amounts of mature adipose tissue (30 HU) interdigitated with higher-density myeloid components, which enhance on contrast administration (Fig. 65-26). Over a quarter of the lesions may exhibit evidence of calcifications, and a large proportion have areas of hemorrhage (Kenney et al, 1998). Macroscopic adipose tissue can also be easily identified within myelolipomas on MRI (Cyran et al, 1996). The presence of macroscopic fat in an adrenal mass is virtually diagnostic of a myelolipoma. Nevertheless, exceedingly rare exceptions exist, and adrenal lipomas, teratomas, angiomyolipomas, metastases, and liposarcomas with macroscopic fat on imaging have been reported (Han et al, 1997; Lam and Lo, 2001). Careful interpretation of cross-sectional imaging is mandatory to distinguish an adrenal myelolipoma from an upper pole renal angiomyelolipoma. In contrast to the benign appearance of a myelolipoma, liposarcomas tend to be aggressive lesions that lack regular borders and have a propensity for infiltrating surrounding tissues (Schaeffer and Kavoussi, 2005). When the diagnosis is in doubt, some experts believe that percutaneous biopsy may be helpful (Han et al, 1997).

As discussed earlier, although myelolipomas are themselves metabolically silent, they have been associated with metabolically active adenomas and pheochromocytomas that may not be readily differentiated on imaging. Therefore it is not unreasonable to perform a standard adrenal metabolic workup in the rare patient who is diagnosed with a myelolipoma (Daneshmand and Quek,

Figure 65-26. Precontrast (A) and postcontrast (B) axial cuts of a computed tomography scan demonstrating a right 6-cm × 3.5-cm adrenal myelolipoma in a 76-year-old, otherwise asymptomatic woman. (Courtesy Dr. Rosalia Viterbo, Fox Chase Cancer Center, Philadelphia.)

2006; Patel et al, 2006). Nevertheless, some experts believe a metabolic workup is necessary only when the index of suspicion for a concomitant metabolically active tumor is high (Han et al, 1997). The NIH consensus panel on adrenal incidentaloma concluded that myelolipoma can be regarded as an exception to the mandatory metabolic workup of a newly discovered adrenal mass (Grumbach et al, 2003).

Treatment. Classically asymptomatic myelolipomas are treated conservatively. No standard protocols for reimaging exist, but serial reevaluation with ultrasonography or CT every several years has been suggested (Han et al, 1997). Surgery is usually reserved for symptomatic lesions (Schaeffer and Kavoussi, 2005).

Prognosis. Tumor growth rates vary. Not only do some lesions remain stable, but some may actually decrease in size over time (Han et al, 1997). Based on available literature, resections are considered definitive. As discussed previously, although spontaneous rupture of myelolipomas has been reported, this event appears to be extremely rare and, on average, has been reported in lesions larger than 10 cm (range 6.3 to 14.7 cm) (Russell et al, 2000).

Summary. Myelolipoma is a rare lesion of the adrenal gland that contains hematopoietic elements and mature adipose tissues. Extra-adrenal lesions have also been reported. In general, lesions do not require resection and follow a benign clinical course.

KEY POINTS: MYELOLIPOMA

- Myelolipomas possess tissue components identical to healthy bone marrow.
- The clinical course is benign, and surgery is indicated only for extremely large or symptomatic lesions.

Ganglioneuroma

Overview and Epidemiology. Ganglioneuromas are extremely rare benign neuroectodermal neoplasms that are composed of ganglion and Schwann cells (Enzinger and Weiss, 1995). Although uncommon, the diagnosis must be considered during the evaluation of an adrenal mass (Mawaja et al, 2007). In one large series (N = 88), 21% of cases arose from the adrenal gland itself. Other sites of origin included the mediastinum (39%) and retroperitoneum (31%), and isolated cases occurred in the pelvis and neck (Enzinger and Weiss, 1995). The tumor appears to have a predilection for the young, with only 20% of cases affecting individuals over age 40, and some 50% of cases found in patients 10 to 29 years of age (Enzinger and Weiss, 1995).

Pathophysiology/Clinical Characteristics. Ganglioneuromas are benign, but isolated cases of ganglioneuromas undergoing malignant transformation have been reported (Enzinger and Weiss, 1995). Furthermore, cases of peripheral nerve sheath tumors (PNST) arising within ganglioneuromas, and composite tumors of ganglioneuroma and pheochromocytoma, also exist in the literature (Radin et al, 1997). It is interesting to note that reports of ganglioneuroma cells in lymph nodes surrounding an apparently benign tumor exist, and some authors presume that such cases represent neuroblastomas that have matured (Enzinger and Weiss, 1995).

Tumors can grow extremely large and have a propensity to encase vessels without impinging on the vessel lumen (Radin et al, 1997). Ganglioneuromas have been reported to secrete vasoactive intestinal polypeptide (VIP), and some patients complain of diarrhea (Enzinger and Weiss, 1995). Nevertheless, the majority of individuals with ganglioneuromas are largely asymptomatic (Radin et al, 1997).

Diagnostic Tests. On both enhanced and unenhanced CT, ganglioneuromas exhibit attenuation less than that of muscle (Radin et al, 1997). Calcifications within the tumor are not uncommon and have been reported to be present in as many as a third of ganglioneuromas (Enzinger and Weiss, 1995; Radin et al, 1997). Some authors have suggested that a metabolically silent adrenal mass with

unenhanced attenuation of less than 40 HU and presence of stippled calcifications should raise suspicion for a ganglioneuroma (Mawaja et al, 2007).

Treatment and Prognosis. Because the diagnosis of ganglioneuroma is nearly always made on resection, natural history of unresected ganglioneuromas has not been clearly defined. Nevertheless, the urologist must be aware that the tumors can grow quite large and can surround critical structures such as retroperitoneal vessels (Radin et al, 1997).

Summary. Ganglioneuromas are rare tumors that can arise from the adrenal gland. Diagnosis is largely pathologic, and the clinical course is nearly always benign.

KEY POINT: GANGLIONEUROMA

- Ganglioneuromas are rare, benign tumors that tend to occur in the young and can grow to encase critical structures.

Adrenal Cysts

Overview and Epidemiology. Adrenal cysts have been noted in 0.064% to 0.18% of patients in autopsy series and account for 1% to 22% of incidentally detected adrenal lesions (Elsayes et al, 2004; Guo et al, 2007; Song et al, 2008; Wedmid and Palese, 2010). Cystic adrenal lesions can be diagnosed throughout life and as early as the prenatal period. Cyst size can range widely from several millimeters to greater than 20 cm, with either unilocular or multilocular components. Although the majority of adrenal cysts are unilateral, bilateral cysts have been noted in 8% to 10% of cases (Rozenblit et al, 1996). An increased incidence of adrenal cysts has been noted in women, with a peak incidence between the third and sixth decades of life (Sanal et al, 2006). Several medical conditions have been associated with adrenal cysts, including polycystic renal disease, Klippel-Trénaunay-Weber syndrome, and Beckwith-Wiedemann syndrome (Erickson et al, 2004).

Pathophysiology. Four histologic types of adrenal cysts have been described: pseudocysts, endothelial cysts, epithelial cysts, and parasitic cysts. Among these, the most common are pseudocysts and endothelial adrenal cysts. Adrenal pseudocysts do not possess a cellular lining and are believed to be the result of previous intra-adrenal hemorrhage or infarction in most cases. Endothelial cysts lack proliferating endothelium and include lymphangiomatous and angiomatous subtypes. Epithelial cysts are lined by a true epithelium and can be further characterized as glandular cysts, embryonal cysts, and cystic adenomas based on pathogenesis. Parasitic adrenal cysts may occur in association with disseminated *Echinococcus* infections; however, it is extremely rare for a parasitic adrenal cyst to be the only site of infection (Otal et al, 1999; Guo et al, 2007; Wedmid and Palese, 2010).

It can be difficult to distinguish a benign adrenal cyst from cystic adrenal neoplasms. This is especially true of adrenal neoplasms with associated hemorrhage or cystic degeneration, which may radiographically resemble an adrenal pseudocyst. In a series of 41 adrenal lesions macroscopically characterized as cysts, 7 were associated with adrenal neoplasms, including 2 ACCs, 2 adenomas, and 3 pheochromocytomas (Erickson et al, 2004). Furthermore, 6 of the 7 adrenal neoplasms in this series were associated with adrenal pseudocysts. A review of multiple series accounting for 515 adrenal cysts noted that 7% of the lesions were associated with malignancy, all of which were pseudocysts (Neri and Nance, 1999). In addition, cases of cystic adrenal carcinoma and pheochromocytomas have been reported (Rozenblit et al, 1996). Compared with benign cysts, cystic adrenal neoplasms tend to be larger (>7 cm) and have thicker walls. In considering the reported incidence of malignancy associated with adrenal cysts, it should be noted that histology in most series is based on surgical specimens, so the incidence of malignancy may be overestimated because small radiographically benign lesions likely remain unresected.

Figure 65-27. Unenhanced computed tomography scan of a right adrenal cyst. Stippled calcifications within the cyst wall are not unusual in these lesions, as can be seen in this particular lesion.

Clinical Characteristics. Although most adrenal cysts are diagnosed incidentally, some become large in size and are symptomatic on presentation. The origin of large adrenal cysts is often difficult to distinguish from other organs, including the kidney, pancreas, spleen, and liver (Otal et al, 1999).

Diagnostic Tests. Although the majority of adrenal cysts are benign and nonfunctional, routine endocrinologic evaluation should be performed to exclude active lesions. Owing to the relative rarity of adrenal cysts, well-defined diagnostic criteria have not been established. The suggested radiographic criteria for diagnosing an adrenal cyst include a well-defined, sharply marginated mass of fluid attenuation without any evidence of enhancement (Fig. 65-27). Cysts with higher fluid attenuation (>30 HU) may be attributed to hemorrhage, intracystic debris, or calcification (Rozenblit et al, 1996; Sanal et al, 2006). The presence of peripheral calcifications has been noted in 15% to 70% of adrenal cysts (Song et al, 2008). Calcifications are typically rimlike, but occasionally will be nodular in appearance (Rozenblit et al, 1996). When evaluated with MRI, simple cysts will appear hypointense on T1-weighted images and hyperintense on T2-weighted images. Unfortunately, radiographic criteria alone cannot rule out malignancy in adrenal cystic lesions; thus cyst aspiration or surgical excision is often performed to rule out malignancy. Aspiration of cystic adrenal lesions should be performed only after chemical evidence of pheochromocytoma has been excluded. Adrenal cyst aspiration may be both diagnostic and potentially therapeutic in select patients (Pradeep et al, 2006). If aspiration is performed, the collected fluid should be sent for Gram stain, cytology, triglycerides, cortisol, and amylase (for left-sided cysts). In addition, a contrast injection of the cyst cavity (cystogram) can be performed at the time of aspiration to evaluate the cyst wall texture.

Treatment. Factors influencing the treatment of adrenal cysts include functional status, chances of incidental malignancy, and cyst-related symptoms. With the known, albeit low, risk of associated malignancy with cystic adrenal lesions, active surveillance must be done with caution. Small, asymptomatic thin-walled lesions containing homogeneous near-water attenuation may be safely observed, and future surveillance of cystic lesions is warranted (Rozenblit et al, 1996). Adrenal cysts that are heterogeneous, larger than 5 cm, thick walled, or symptomatic warrant further evaluation and surgical excision (Wedmid and Palese, 2010). Because of the known risk of associated malignancy, simple decortication is not advocated and should be undertaken with caution. Owing to the inadequacies of radiographic evaluation, surgical resection remains the standard of care in patients with a normal-appearing contralateral adrenal gland.

Prognosis. The prognosis and subsequent follow-up after resection of an adrenal cyst are dependent on histology. Benign adrenal cysts warrant follow-up to monitor potential reaccumulation, and warrant re-treatment if symptoms return. Adrenal cysts associated with malignancy require follow-up in accordance with the malignant histology detected.

Summary. Adrenal cysts are rare, and their diagnosis can be challenging. Symptomatic adrenal cysts should be surgically removed, whereas small nonfunctional asymptomatic lesions with benign radiographic appearance may be treated conservatively with regular follow-up.

KEY POINT: ADRENAL CYSTS

- Because of the known chance of associated malignancy, observation of adrenal cysts must be done with caution.

Benign Pheochromocytoma. Benign pheochromocytomas are discussed in the section on pheochromocytoma under Disorders of Increased Adrenal Function.

EVALUATION OF ADRENAL LESIONS IN UROLOGIC PRACTICE

In urologic practice, the evaluation of adrenal pathology is typically in the setting of patients referred with a diagnosis of a new adrenal mass or in existing patients in whom a new adrenal mass is discovered incidentally. Occasionally, patients are identified by astute clinicians based on clinical symptoms in the absence of prior radiographic identification of an adrenal lesion. This section of the chapter reviews clinically relevant evaluation and management of adrenal masses. It is important to note that the pregnant patient diagnosed with an adrenal mass requires a carefully planned, multidisciplinary, tailored approach. This subject matter is beyond the scope of this chapter; however, reviews on this topic are available (Harrington et al, 1999; Lindsay and Nieman, 2005b; Klibanski et al, 2006; Lindsay and Nieman, 2006).

Overview of the Adrenal Incidentaloma

Adrenal incidentalomas are unsuspected adrenal masses greater than 1 cm in diameter identified on cross-sectional imaging performed for seemingly unrelated causes. Strictly speaking, patients who are undergoing a staging evaluation for another malignancy or who are later found to have symptoms relating to the adrenal lesion are excluded from the term *adrenal incidentaloma*, given the possible relationship of the primary indication for the study and the adrenal lesion (Young, 2000, 2007b; Mazzaglia and Monchik, 2009). The frequency of adrenal incidentalomas is relatively high, with contemporary imaging series reporting an incidence of approximately 5% (Song et al, 2008), similar to that found in historical autopsy data (Commons and Callaway, 1948; Russell et al, 1972). The incidence of the incidental adrenal mass increases with age, with a risk of less than 0.5% in individuals in their 20s and up to 7% in those 70 years of age or older (Young, 2000).

It is important to emphasize that “incidental” does not mean “insignificant.” Table 65-15 summarizes collective data available regarding pertinent clinical characteristics of over 2000 newly discovered adrenal lesions and demonstrates that nearly 20% of adrenal incidentalomas are found to be potential surgical lesions. The two characteristics of primary clinical relevance are imaging and metabolic activity or functional status. Biopsy is rarely indicated but can be a useful tool in specific clinical circumstances. This section of the chapter describes in details the clinical indications and processes of imaging, biopsy, and metabolic testing.

TABLE 65-15 Characteristics of Incidental Adrenal Masses as Described in a Systematic Review of Published Series of Adrenal Incidentalomas That Include 20 or More Patients (N = 2005)

ADRENAL LESION	PERCENT OF TOTAL (N = 2005)
Metabolically active	11.2%
Cortisol-producing adenoma	5.3%
Aldosterone-producing adenoma	1.0%
Pheochromocytoma	5.1%
Malignant	7.2%
Adrenocortical carcinoma	4.7%
Metastasis	2.5%
TOTAL POTENTIALLY SURGICAL LESIONS	18.4%

Imaging of Adrenal Masses

Imaging Modalities

Appropriate management and follow-up of the adrenal incidentaloma largely depend on ordering the proper test, carrying out accurate image-acquisition protocols, and interpreting the information obtained. Urologists must be well versed in adrenal imaging modalities and limitations and be able to speak knowledgeably to their radiology colleagues. Numerous imaging modalities can be used to assess both morphologic and functional features of adrenal masses. This section summarizes the salient features of each imaging modality as it pertains to characterization of adrenal incidentalomas. Please also refer to the section on adrenal lesions for details regarding imaging characteristics of each specific type of adrenal lesion.

Ultrasonography. Ultrasonography is a suboptimal imaging modality for detecting and fully characterizing adrenal lesions. Nevertheless, many incidentalomas will be discovered on ultrasound imaging performed for unrelated reasons. Indeed, in parts of the world where ultrasonography is used as the primary imaging modality, the majority of adrenal incidentalomas are discovered through use of this modality (Bhargava et al, 2008). Moreover, in series wherein ultrasonography is responsible for identifying individuals with adenomas, right-sided lesions appear to be more common, whereas ultrasonography is less sensitive in identifying left-sided adrenal lesions than those in the right gland, based on anatomic differences. On the right, the IVC and liver provide a better window to the adrenal gland on ultrasonography, whereas on the left the adrenal can be overlooked or mistaken as part of the splenic, pancreatic, para-aortic lymphatic, or gastric anatomy (Barzon et al, 2003).

Computed Tomography and Magnetic Resonance Imaging. CT and MRI permit cross-sectional and reconstructed anatomic image characterization of the adrenals and serve as the cornerstone for adrenal evaluation. Size, laterality, homogeneity, density, vascularity (enhancement and washout), and anatomic relationships can be accurately assessed using these modalities. Indeed, the size of an adrenal lesion, a characteristic reliably assessed by cross-sectional imaging, is a primary factor driving management decisions (see discussion in the section on [size and growth](#)). Often the differential diagnosis of an adrenal lesion can be immediately narrowed based on the imaging characteristics. For instance, the presence of macroscopic fat identifies an adrenal myelolipoma, whereas large heterogeneous masses that invade surrounding structures are

most indicative of adrenal adenocarcinomas (Cyran et al, 1996). Adrenal cysts and acute or subacute hemorrhage also exhibit characteristic imaging findings (Burks et al, 1992). Nevertheless, most adrenal incidentalomas are small homogeneous masses with regular contours that cannot be immediately given a pathologic label. Further characterization of these common lesions relies on the ability of modern cross-sectional imaging to identify the presence of intracytoplasmic lipid that differentiates a benign adrenal adenoma from other adrenal pathology (Korobkin et al, 1996b). Although adenomas can be differentiated from nonadenomas based on this single imaging characteristic, the need for a metabolic workup is not eliminated based on identification of lipid within an adrenal mass. Radiographic differentiation between metabolically functional and nonfunctioning adenomas has been investigated, and, to date, no reliable radiographic test or characteristic is sensitive enough to obviate endocrinologic evaluation based solely on imaging (Korobkin et al, 1996b; Fujiyoshi et al, 2003; Hussain and Korobkin, 2004).

Unenhanced Computed Tomography. An unenhanced CT scan is the first, and perhaps single best, and most easily interpreted test for intracellular lipid and therefore can diagnose an adrenal adenoma in more than 70% of cases. Low attenuation (<10 HU) on unenhanced CT corresponds to high intracytoplasmic lipid content and is diagnostic for an adrenal adenoma (Lee et al, 1991; Korobkin et al, 1996b). Using a threshold of 0 HU or less, there is 100% specificity for an adrenal adenoma, meaning that if the lesion meets this criterion, it is always an adenoma. Unfortunately, the sensitivity of noncontrast CT density measurements is imperfect, meaning that not all adenomas will meet this criterion. Indeed only 41% of adenomas exhibit an attenuation of 0 HU (Boland et al, 1998), and therefore a threshold of 10 HU is currently used. This cutoff affords a sensitivity of 71% and a specificity of 98% for the diagnosis of adrenal adenomas (Boland et al, 1998, 2008). In other words, 98% of lesions that exhibit an attenuation of 10 HU or less on noncontrast CT are adrenal adenomas, whereas less than 30% of adrenal adenomas are lipid poor (also known as *atypical adenomas*) and exhibit an attenuation of greater than 10 HU. Similar test characteristics have been confirmed in purely surgical series (Hamrahian et al, 2005). In urologic practice, this criterion on unenhanced CT is quite useful, because the vast majority of renal imaging for stones or lesions of the upper urinary tracts includes an unenhanced precontrast phase. Despite the high specificity of the 10-HU cutoff, few low-density (<10 HU) pheochromocytomas have been reported, underscoring the importance of a metabolic workup for all adrenal lesions (Blake et al, 2003, 2005). It should be mentioned that in an era of digital radiology, density measurements of adrenal lesions can easily be undertaken at the time of evaluation, even when the interpreting radiologist may not provide the values in the dictation. Diligence in this regard by the clinician is essential to avoid additional unnecessary imaging tests, even if improperly recommended.

Enhanced Computed Tomography. Some adrenal masses may be discovered on contrast-enhanced imaging without the benefit of precontrast films. Unfortunately, the diagnostic information that can be obtained from attenuation values of these single-phase studies (approximately 1 minute after the contrast bolus) is limited. Unlike unenhanced CT, there is tremendous overlap in postcontrast attenuation values of adenomas and nonadenomas (Korobkin et al, 1996a; Szolar and Kammerhuber, 1998).

Nevertheless, enhanced CT may indeed contain diagnostic information that is helpful. Data reveal that morphologic features such as irregular margins and an enhancing rim can be quite specific for malignancy (Song et al, 2013). Furthermore, histogram analysis of the lesion's region of interest (ROI) may be useful in identifying lipid-rich adenomas on enhanced CT. This technique is available on most modern workstations, and it graphs the quantity of pixels in an ROI against their attenuation value (Boland et al, 2008). Some suggest that if more than 10% of pixels exhibit a density below 0 HU, the lesion is likely an adenoma (Bae et al, 2003; Boland et al, 2008). Combination of a histogram analysis and ¹⁸F-FDG-PET CT also harbors promise (Perri et al, 2011).

Computed Tomography Washout Study. Approximately 30% of adrenal adenomas exhibit an attenuation of greater than 10 HU on unenhanced CT owing to their lower lipid content. These “atypical adenomas” are indistinguishable from nonadenomas on noncontrast CT density measurements alone (Boland et al, 1998). Fortunately, lipid-poor adenomas possess identical properties to lipid-rich adenomas regarding their rapid loss (washout) of enhancement after CT contrast load (Caoili et al, 2000; Pena et al, 2000). Indeed, in the last decade, washout of contrast enhancement has become a routine technique to differentiate lipid-poor adenomas from other adrenal lesions (Korobkin et al, 1998; Szolar and Kammerhuber, 1998; Szolar et al, 2005). An absolute percent washout (comparing noncontrast values with 15-minute postcontrast density values) of greater than 60%, or a relative percent washout (RPW) (comparing arterial phase density measurements with 15-minute postcontrast density values) of greater than 40% on delayed (washout) imaging, is indicative of adenoma (Fig. 65-28) (Caoili et al, 2002; Boland et al, 2008). Remarkably, test characteristics for these CT washout studies are highly sensitive and specific (Boland et al, 2008). Figure 65-29 summarizes when CT washout studies should be used and how the percent washout is calculated. It is important to note, however, that washout characteristics may have limitations in differentiating lipid-poor adenomas from RCC and hepatocellular carcinoma metastases (Choi et al, 2013). Furthermore, data on washout characteristics of ACC are limited, largely because of the large size at presentation and lack of necessity in performing such studies. Although, classically, ACC can be differentiated from adenoma on 15-minute CT washout studies, some exceptions have been reported (Simhan et al, 2012a).

Reports on washout studies using a 10- instead of a 15-minute delay exist. Originally, an RPW of greater than 50% was believed to be necessary to diagnose adenomas using such protocols (Pena et al, 2000). Although some reports suggest that just as with a 15-minute delayed study, an RPW of more than 40% is sufficient (Blake et al, 2005), imaging experts currently recommend use of 15-minute delayed protocols, despite the potential added efficiency of a 10-minute study (Boland et al, 2008; Boland, 2010b).

Given these data, it is imperative that the knowledgeable urologist order a proper adrenal CT study to include noncontrast 5-mm images through the adrenal with enhanced (1-minute postbolus imaging) and 15-minute washout imaging and that he or she speak to the radiologists to ensure that the test uses the proper protocol. In the absence of a properly performed test, nondiagnostic images may lead to a recommendation for subsequent unnecessary and anxiety-provoking tests.

Magnetic Resonance Imaging. Similar to adrenal imaging by CT, MRI of the adrenal incidentaloma relies on its ability to accurately quantify the lesion’s lipid content. Whereas CT uses unenhanced attenuation to identify lipid-rich adenomas, MRI harnesses the interference between signal collected from fat and water tissue to evaluate for intracellular lipid content (Hussain and Korobkin, 2004). On such opposed phase chemical shift imaging, signal intensity loss on out-of-phase sequences, when compared with in-phase imaging, signifies the presence of intracellular lipid and definitively identifies the lesions in question is an adenoma (Korobkin et al, 1996b; Namimoto et al, 2001). The loss of signal intensity can be quantified by several methods (e.g., use of the spleen as an internal reference); however, in clinical practice, qualitative

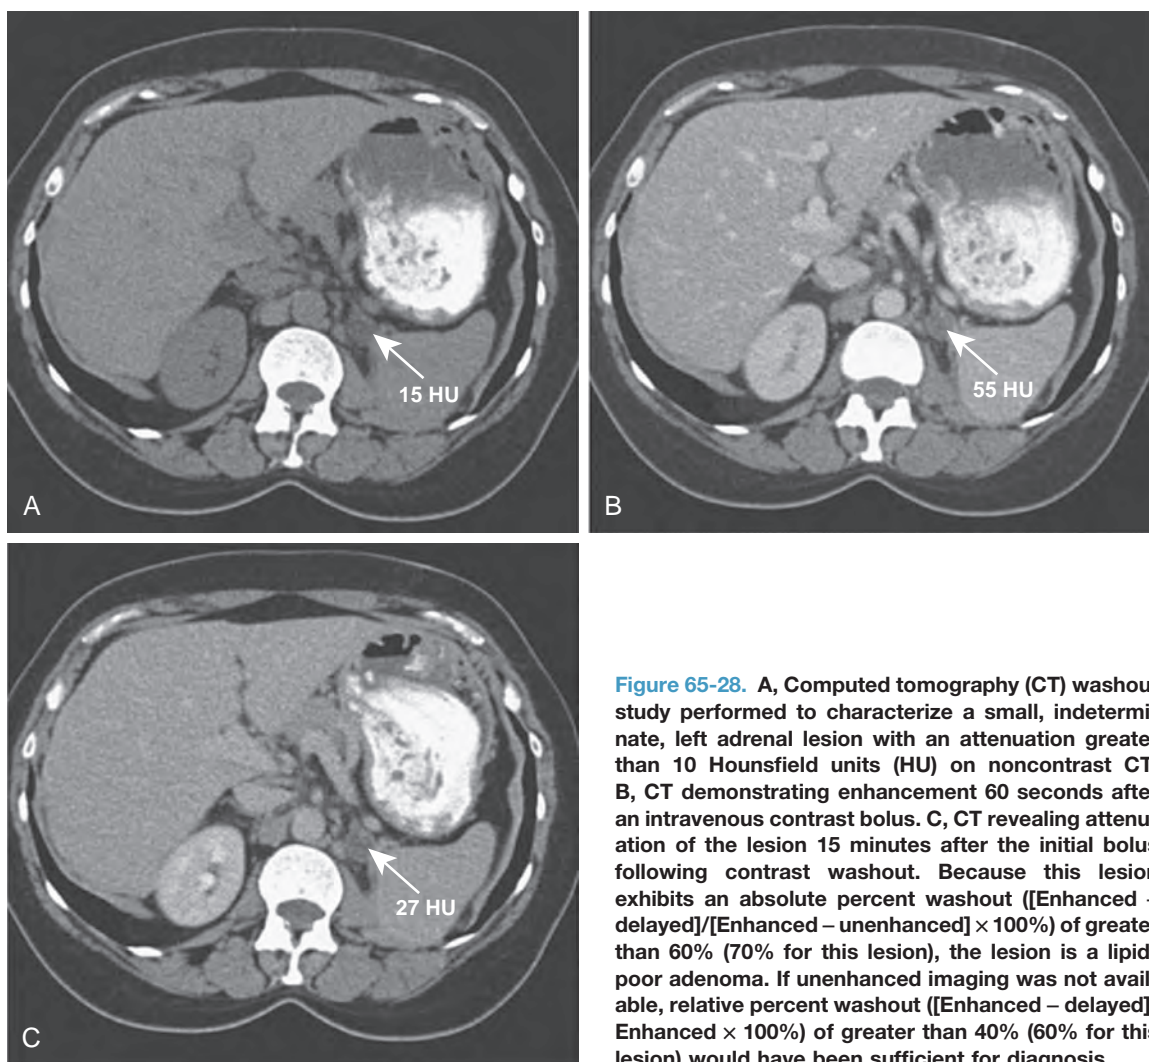

Figure 65-28. A, Computed tomography (CT) washout study performed to characterize a small, indeterminate, left adrenal lesion with an attenuation greater than 10 Hounsfield units (HU) on noncontrast CT. B, CT demonstrating enhancement 60 seconds after an intravenous contrast bolus. C, CT revealing attenuation of the lesion 15 minutes after the initial bolus following contrast washout. Because this lesion exhibits an absolute percent washout $\left(\frac{[\text{Enhanced} - \text{delayed}]}{[\text{Enhanced} - \text{unenhanced}]} \times 100\%\right)$ of greater than 60% (70% for this lesion), the lesion is a lipid-poor adenoma. If unenhanced imaging was not available, relative percent washout $\left(\frac{[\text{Enhanced} - \text{delayed}]}{\text{Enhanced}} \times 100\%\right)$ of greater than 40% (60% for this lesion) would have been sufficient for diagnosis.

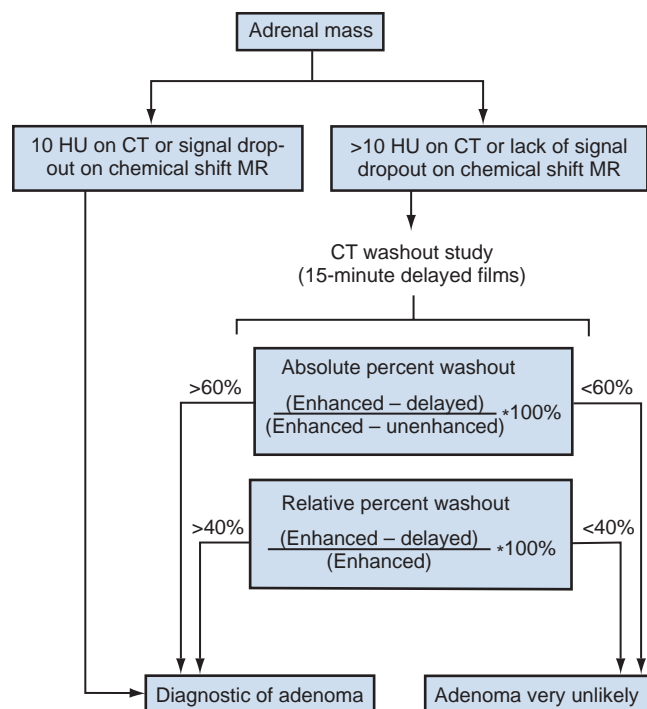

Figure 65-29. Summary of evaluation of adrenal mass using modern cross-sectional imaging. CT, computed tomography; HU, Hounsfield units; MR, magnetic resonance.

assessments are most often used (Outwater et al, 1996; Fujiyoshi et al, 2003; Boland et al, 2008). Most reports demonstrate that the test characteristics of chemical shift MRI are similar to those of unenhanced CT, albeit significantly more expensive. Although some reports suggest that MRI may be superior to unenhanced CT in characterizing lipid-poor adenomas (Haider et al, 2004; Israel et al, 2004), most experts believe that the two modalities are largely equivalent (Boland, 2010b). Nevertheless, CT washout studies are considered the gold standard and appear to surpass opposed phase chemical shift MRI in their sensitivity for identifying adenomas (Caoili et al, 2000; Hussain and Korobkin, 2004; Park et al, 2007a; Boland et al, 2008; Boland, 2010a, 2010b). It is important to note that gadolinium-enhanced MRI washout studies do not exhibit the diagnostic strength of iodine-based CT washout studies and are not currently used in clinical practice. This shortcoming of MRI may be explained by the fact that gadolinium-induced signal intensity is less dose-dependent than enhancement from iodinated contrast on CT imaging (Hussain and Korobkin, 2004).

Functional Imaging. The high diagnostic accuracy provided by biochemical evaluation and cross-sectional radiographic imaging of adrenal incidentalomas limits the indications for the routine use of functional imaging. However, functional adrenal imaging can provide valuable information when the origin of the adrenal tumor is unclear or when malignancy is highly suspected but has not been confirmed with other diagnostic modalities (Avram et al, 2006; Gross et al, 2009).

Radionuclide scintigraphy with the radiolabeled cholesterol analog NP59 can help determine whether or not an adrenal lesion originated in the adrenal cortex or is from another source, because adrenocortical cells demonstrate increased uptake of the cholesterol analog. Based on the pattern of NP59 uptake, adrenal adenomas can be distinguished from other space-occupying lesions of the adrenal gland with high sensitivity and specificity (Kloos et al, 1995, 1997). Although the characterization of lesions greater than 2 cm is limited with planar scintigraphy, the use of SPECT-CT may enhance the ability of NP59 to detect smaller lesions (La Cava et al, 2003). Despite the apparent benefits of NP59 scintigraphy in detecting adrenal adenomas, the test is time-consuming and is not

currently approved by the U.S. Food and Drug Administration. Moreover, it cannot reliably exclude the presence of ACC (Tauchmanova et al, 2004).

Another radiotracer used to identify tumors of adrenocortical origin is carbon-11 (^{11}C)-metomidate. Metomidate is an inhibitor of 11β -hydroxylase and aldosterone synthase that is preferentially taken up by adrenocortical cells (see Fig. 65-3). Although several studies have demonstrated the ability of ^{11}C -metomidate PET to correctly identify tumors of adrenocortical origin, the test is significantly limited by its inability to differentiate benign adrenal adenomas from ACCs (Minn et al, 2004; Hennings et al, 2006).

The role of functional imaging for the diagnosis of pheochromocytoma is limited, given that most pheochromocytomas can be accurately diagnosed with cross-sectional imaging and metabolic evaluation for catecholamines and their metabolites. Therefore ^{131}I -MIBG imaging has a limited role in the routine evaluation of adrenal incidentalomas. MIBG is a functional and structural analog of norepinephrine that is incorporated into catecholamine storage vesicles. Increased uptake of MIBG suggests the presence of a chromaffin tumor, such as a pheochromocytoma or paraganglioma. In a small series of 23 patients with nonfunctioning adrenal masses, ^{131}I -MIBG scintigraphy was performed before pathologic evaluation and demonstrated a sensitivity of 100% and a specificity of 94% in identifying the presence of pheochromocytomas and paragangliomas (Maurea et al, 2001). Although there are alternatives to MIBG imaging for the detection of pheochromocytomas, including ^{18}F -dopamine PET and the somatostatin analog indium-111 (^{111}In)-octreotide, their usefulness in the routine evaluation of adrenal incidentalomas has not been evaluated to date (Mayo-Smith et al, 2001; Timmers et al, 2007a). As discussed previously, ^{18}F -FDG PET is largely replacing MIBG in staging non-MEN-2 patients with known pheochromocytoma (Timmers et al, 2012).

The differentiation of benign and malignant adrenal tumors may be facilitated by the use of ^{18}F -FDG PET. Multiple reports have demonstrated a high sensitivity (93% to 100%) and specificity (80% to 100%) of use of ^{18}F -FDG PET to identify malignant adrenal tumors, including ACCs and metastatic lesions to the adrenal (Yun et al, 2001; Blake et al, 2006; Chong et al, 2006; Boland et al, 2011). However, the use of ^{18}F -FDG PET is best reserved for cases in which CT imaging and clinical data are inconclusive (Boland et al, 2008, 2011). Indeed, some data suggest that CT washout studies are more helpful than ^{18}F -FDG PET in evaluating patients with an adrenal mass and known malignancy (Park et al, 2007b). Nevertheless, caution must be exercised in patients with known RCC and hepatocellular carcinoma, because adrenal metastases from these primary tumors can exhibit iodinated contrast washout characteristics similar to those of lipid-poor adenomas (Choi et al, 2013).

KEY POINTS: IMAGING

- Low attenuation on unenhanced CT (<10 HU) corresponds to high intracellular lipid and is extremely specific for identification of adrenal adenoma.
- MRI is similar in its test characteristics to unenhanced CT.
- CT washout studies are considered the gold standard for adrenal imaging. Rapid loss of contrast enhancement can differentiate even lipid-poor adenomas (approximately 30% of adenomas) from other lesions. Gadolinium-enhanced MRI washout studies do not exhibit the diagnostic strength of iodine-based CT washout studies and are not currently used in clinical practice.
- RCC metastases may exhibit washout characteristics similar to those of lipid-poor adenomas.

Size and Growth

The retroperitoneal space allows for relatively asymptomatic growth of most adrenal lesions, which may reach beyond 20 cm

Figure 65-30. Distribution of benign versus malignant adrenal masses based on lesion size (N = 1322). (Modified from Barzon L, Sonino N, Fallo F, et al. Prevalence and natural history of adrenal incidentalomas. *Eur J Endocrinol* 2003;149:273–85.)

in size before clinically manifesting. Nevertheless, at presentation the median radiographic diameter of an adrenal incidentaloma is approximately 3 cm (Mantero et al, 2000). A relationship does exist between the size of an adrenal lesion and its malignant potential, with larger masses more likely to exhibit adverse clinical and pathologic features (Angeli et al, 1997). Figure 65-30 summarizes the relationship between adrenal mass size and its risk of malignancy in over 1300 reported incidentalomas (Barzon et al, 2003). Masses smaller than 4 cm are considered to possess low malignant potential (2% are adrenal carcinomas) and, if nonfunctional, can be observed safely (Grumbach et al, 2003; Cicala et al, 2008). Masses that exceed 6 cm should be considered malignant until proven benign, which usually requires definitive resection. Management of incidentalomas between 4 cm and 6 cm is more controversial. In this intermediate size range, the rate of malignancy is estimated to be only 6% (Cicala et al, 2008). Nonetheless, in otherwise healthy individuals with acceptable perioperative risk profile, most experts recommend 4 cm as the cutoff diameter that warrants resection (Barry et al, 1998; Mantero et al, 2000; Young, 2000; Thompson and Young, 2003; Young, 2007b). In the largest adrenal incidentaloma series to date (N = 1004), Mantero and colleagues (2000) reported that the 4-cm cutoff afforded a 93% sensitivity and 42% specificity for detecting malignancy. Sensitivity dropped to 74% and specificity rose to 73% when a 6-cm cutoff was applied. It is important to note that the relationship between the radiographic and pathologic size of an adrenal lesion is imperfect, with pathologic assessment usually resulting in a larger measurement (Cerfolio et al, 1993; Kouriefs et al, 2001). Furthermore, administrative data reveal only a weak relationship between tumor size at presentation and rates of concomitant metastatic disease in patients with ACC. Also, although analyses from administrative data sets must be interpreted with caution, a robust relationship between survival and size of localized ACC at resection is difficult to identify (Canter et al, 2013).

The urologic oncologist must remember that the incidence of benign adrenal adenomas increases with age; therefore adrenal lesions in younger patients, even those smaller than 4 cm, must be managed with greater caution than similar lesions in an older patient. Likewise, lesions larger than 4 cm in older patients with significant comorbidities may be better served with observation than resection (Young, 2007b). Moreover, the radiographic characteristics of individual adrenal lesions (regularity of borders, enhancement) must be considered in addition to the lesion's size when deciding whether to treat. In the absence of level 1 evidence, large population-based reports must be integrated with sound clinical judgment.

The growth kinetics of unresected adrenal lesions should be followed, although most lesions that are resected because of increased growth kinetics ultimately prove benign. In a prospectively followed multi-institutional Swedish cohort (N = 229, median follow-up 25 months), 7.4% (17) of masses grew at least 5 mm, with 5.2% (12) adding at least 1 cm to their diameter. All patients who underwent resection because of an increase in lesion size exhibited benign pathology (Libe et al, 2002). Similarly, an earlier review of the literature (N = 873) revealed that at a mean follow-up of 3 years, 9% of adrenal incidentalomas grew over 1 cm in diameter and a smaller number decreased in size. In this series, only one lesion proved malignant. The authors concluded that the rate of malignant transformation of adrenal incidentalomas is approximately 1 in 1000 (Barzon et al, 2003). Reimaging at 6, 12, and, as possible, 24 months is currently recommended to verify oncologic indolence (Grumbach et al, 2003; Young, 2007b). Suspicious and unusual tumors may require imaging at earlier or more frequent intervals, whereas small (<2 cm) homogeneous, well-circumscribed, nonfunctional lesions can be followed less closely (Young, 2007b). A rather arbitrary criterion of 1 cm of growth has been proposed as an indication for resection; however, the patient must be counseled that the chance of malignancy is low if growth kinetics are flat (Young, 2007b).

KEY POINTS: SIZE AND GROWTH

- Masses larger than 6 cm should be considered malignant until proved otherwise. Although management of masses between 4 cm and 6 cm is controversial, thought leaders in the field advise that in otherwise healthy individuals, masses 4 cm or larger should be resected.
- Kinetics of growth should be followed. The current recommendation is to resect masses that grow over 1 cm; however, incidence of malignancy among these patients is low.

Biopsy of Adrenal Masses

Overview

The role of adrenal biopsy has been limited for the following reasons: (1) modern imaging in the context of clinical characteristics affords superb diagnostic capabilities, (2) histologically, adenomas cannot be reliably differentiated from adrenal carcinomas, and (3) adrenal biopsy is not without risk (Thompson and Young, 2003; Young, 2007b). Nevertheless, it is useful to review data that are available with regard to safety and diagnostic usefulness of adrenal biopsy, and the procedure can occasionally be a useful tool in the diagnostic armamentarium of the adrenal surgeon.

Test Characteristics of Biopsy

Welch and colleagues (1994) reported on 277 percutaneous biopsies performed at the Mayo Clinic. Most biopsies in the series were performed in patients with a known nonadrenal malignancy. The authors report a sensitivity of 81% and specificity of 99%. The accuracy of right-sided biopsies was higher than those on the left (94% vs. 87%). Larger biopsy needles (18 or 19 gauge) resulted in better diagnostic yield and equivalent complication rates when compared with biopsies performed with smaller needles.

The reported positive predictive value of adrenal biopsy is high, meaning that a positive biopsy for malignancy has a high correlation on final pathology. This is especially relevant in patients with a history of an unrelated primary malignancy and in whom an adrenal metastasis is suspected (Silverman et al, 1993; Harisinghani et al, 2002). Although the overall specificity is imperfect, in the same clinical scenario the test's negative predictive value is nevertheless impressive when nondiagnostic biopsies are excluded (Silverman et al, 1993; Harisinghani et al, 2002). In a series of 225 adrenal

biopsies performed in patients with a known primary malignancy at Massachusetts General Hospital, 18% of biopsy specimens demonstrated adrenal tissue without evidence of malignancy. The authors reported the negative predictive value of these negative biopsy findings based on lack of tumor growth at follow-up, autopsy findings, or a rebiopsy result of 100%, although selection and research biases may have existed (Harisinghani et al, 2002). In skilled hands, nondiagnostic biopsies appear infrequent when the majority of sampling is performed with 18-gauge needles (Paulsen et al, 2004).

The probability of a positive adrenal biopsy for metastatic disease appears highest in patients with known lung carcinoma (>90%) and RCC (80%) (Mazzaglia and Monchik, 2009). In contrast, an adrenal mass in a patient without a previous history of malignancy and without evidence of a synchronous nonadrenal mass is highly unlikely to be present as a metastasis (Lutz et al, 2000). Biopsy in this setting is rarely helpful. Instead, other criteria, such as radiographic morphology and size, must be used to characterize adrenal masses in such patients (Thompson and Young, 2003; Mazzaglia and Monchik, 2009).

Complications of Biopsy

The complication rates of adrenal biopsies in some large series are as low as 2.8% (Welch et al, 1994). Bleeding is the most common postbiopsy issue, with pneumothoraces and hemothoraces also being reported (Silverman et al, 1993; Welch et al, 1994; Quayle et al, 2007). Needle-track seeding in patients with ACC remains a concern, and some authors suggest that biopsy should be avoided in patients in whom adrenal carcinoma is suspected (Quayle et al, 2007). Surgically, there has been a suggestion that biopsy, especially if followed by hemorrhage, can complicate or even prevent laparoscopic resection (Quayle et al, 2007).

The NIH consensus statement mandates that the possibility of pheochromocytoma be metabolically excluded before biopsy; percutaneous biopsies of pheochromocytomas have been reported to result in life-threatening hypertensive crises (Grumbach et al, 2003; Quayle et al, 2007). It is interesting to note that inadvertent biopsy of pheochromocytomas has resulted in no ill effects in some patients (Quayle et al, 2007); however, in real-world practice, due diligence to rule out pheochromocytoma before biopsy is prudent (Mazzaglia and Monchik, 2009).

Clinical Usefulness of Biopsy

Despite the fact that adrenal biopsies—when used to differentiate benign from metastatic disease—afford favorable accuracy, some clinicians argue that most adrenal biopsies performed today are unnecessary (Quayle et al, 2007; Mazzaglia and Monchik, 2009). For instance, Quayle and colleagues retrospectively reviewed their experience with patients who were sent to their tertiary referral center after an adrenal biopsy performed in the community. The researchers concluded that in no case did the biopsy affect the clinical management of these patients. Moreover, these and other investigators have raised the issue of radiology reports recommending adrenal biopsies or stating that the lesions are “amenable” to biopsy. The authors suggested that such language in radiology reports must be strongly discouraged, because it leads to unnecessary and, at times, deleterious procedures by physicians who are not familiar with standard management of the adrenal mass (Quayle et al, 2007; Mazzaglia and Monchik, 2009).

In conclusion, adrenal biopsy should be pursued only when limitations of imaging have been reached and when the physician and patient are certain that the result of biopsy will influence management. Indeed, perhaps the biggest role for adrenal mass biopsy is in patients with primary malignancies that have potentially recurred in the adrenal gland and whose management will be affected by the biopsy results. Figure 65-31 summarizes the salient points that must be considered when making a decision regarding whether to perform a biopsy of a patient's adrenal mass.

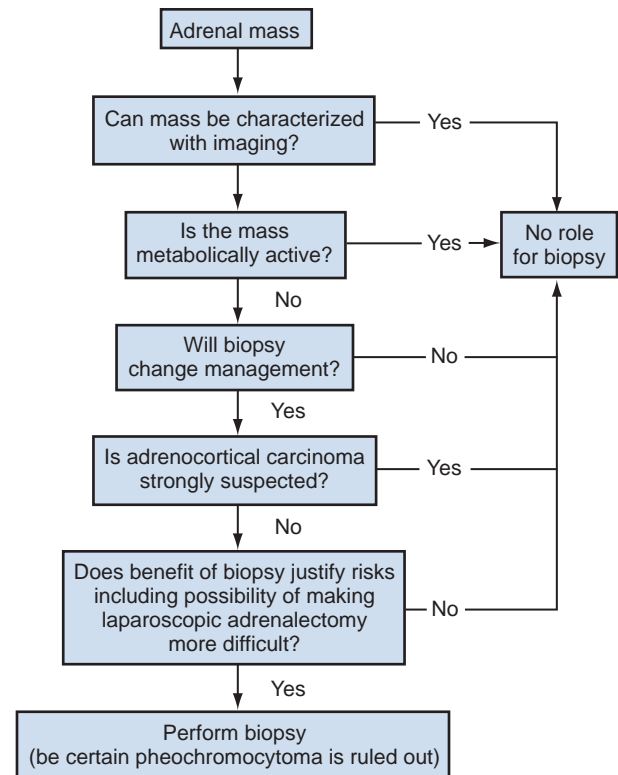

Figure 65-31. Algorithm summarizing decision making regarding whether to subject the patient to an adrenal biopsy. Perhaps the most clinically valuable role for adrenal mass biopsy is in patients with primary malignancies that have potentially recurred in the adrenal gland and whose management will be affected by the biopsy results.

KEY POINTS: BIOPSY OF ADRENAL MASSES

- When used to differentiate benign from metastatic disease, adrenal biopsy carries favorable test characteristics.
- Always exclude possibility of pheochromocytoma before biopsy.

Assessment of Function of Adrenal Masses

Overview

The NIH consensus statement recommends metabolic testing for all adrenal incidentalomas (Grumbach et al, 2003). This recommendation is supported by the observation that more than 10% of adrenal incidentalomas are metabolically active (see Table 65-15). Current practice is to test all new adrenal masses for cortisol and catecholamine hypersecretion. In patients with a history of hypertension, aldosterone hypersecretion should also be assessed (Grumbach et al, 2003; Young, 2007b). Despite this recommendation as a standard of care, routine clinical practice remains inadequate in this domain, whereas it is estimated that more than 80% of adrenal masses do not receive appropriate evaluation (Eldeiry and Garber, 2008).

Testing for Cortisol Hypersecretion

A systematic review of the literature reveals that 5% to 8% of adrenal incidentalomas produce excessive glucocorticoids (Young, 2000; Barzon et al, 2003). The NIH consensus guidelines state that all adrenal lesions should be tested for glucocorticoid hypersecretion (Grumbach et al, 2003). Three first-line tests are available to

screen patients with incidentalomas for Cushing syndrome: (1) LD-DST, (2) a late-night salivary cortisol test, and (3) a 24-hour UFC evaluation. A meta-analysis of the published literature demonstrates that these tests afford relatively equivalent accuracy; however, the UFC and the LD-DST are supported by more abundant evidence than the late-night salivary cortisol approach (Elamin et al, 2008). Nonetheless, reports suggest that UFC is not sufficiently sensitive to detect subclinical Cushing syndrome (Tsagarakis et al, 2006; Mitchell et al, 2007). Indeed, recent practice guidelines from the Endocrine Society recommend the use of either the LD-DST or the late-night salivary cortisol test to screen patients with adrenal incidentalomas as part of a complete endocrinologic evaluation (Nieman et al, 2008). The section on Cushing syndrome reviews the physiologic rationale for both first-line testing discussed here and other testing that may be necessary. In this section, we review practical considerations of evaluating adrenal incidentalomas for excess glucocorticoid secretion within the scope of urologic practice. As mentioned in prior sections, the physician must verify that exogenous steroids, including creams and nasal sprays, are not in use by the patient before testing.

Overnight Low-Dose Dexamethasone Suppression Test. Administration of low-dose dexamethasone followed by measurement of serum cortisol probes the patient's glucocorticoid negative feedback system (see the section on Cushing syndrome for a discussion of physiology). A patient's failure to suppress cortisol levels after low-dose dexamethasone administration is indicative of Cushing syndrome (Findling and Raff, 2005).

Despite the test's arguably complex physiologic considerations, its administration is remarkably simple. The patient is given a prescription for 1 mg of dexamethasone and instructed to take it between 11 PM and 12 AM (Newell-Price et al, 2006). The next morning, serum cortisol is measured between 8 AM and 9 AM. In patients without hypercortisolemia, the cortisol level should be suppressed below 5 µg/dL (140 nmol/L). Specificity at this threshold is greater than 95% (Nieman et al, 2008). The trade-off, however, is sensitivity. In some reports, up to 18% of patients with Cushing syndrome exhibited false-negative results (Findling et al, 2004). Therefore a threshold suppressed cortisol level of 1.8 µg/dL (50 nmol/L) has been suggested, raising the sensitivity to over 90% (Findling et al, 2004) with a specificity of 80% (Nieman et al, 2008). The test's performance is similar to that of other first-line tests used to diagnose Cushing syndrome and is recommended as an alternative to the late-night salivary cortisol test for initial screening of incidentalomas (Elamin et al, 2008; Nieman et al, 2008).

Unlike 24-hour UFC testing, LD-DST is not affected by the patient's glomerular filtration rate (GFR). Box 65-5 lists the most common pharmacologic agents that can alter testing. Most important, the urologist must be aware that the test can yield as high as a 50% false-positive rate in women using oral contraceptives, because the contraceptives increase total (but not bioavailable) cortisol levels by raising the patient's cortisol-binding globulin concentrations (Nickelsen et al, 1989). Administration of low-dose dexamethasone over a 48-hour period is less practical but may improve accuracy and is preferred by some endocrinologists.

Late-Night Salivary Cortisol. Late-night cortisol measurements probe the perturbation or, in some cases, complete disruption in the diurnal variation of cortisol levels that is seen in Cushing syndrome. The abnormality, even in very mild cases of Cushing syndrome, is the inability to suppress cortisol levels at night (Raff and Findling, 2003; Findling and Raff, 2005). Because late-night serum cortisol measurements are impractical, salivary testing has gained acceptance, because salivary cortisol levels reflect near real-time serum cortisol levels. Measurements of cortisol in saliva samples collected between 11 PM and midnight or at bedtime should not exceed 145 ng/dL when the liquid chromatography–tandem mass spectrometry (LC-MS/MS) assay is used (Nieman et al, 2008). The sensitivity and specificity of the test exceed 90% and are similar to both UFC and LD-DST; however, a large meta-analysis concluded that the data supporting salivary cortisol testing, to date, are inferior to the data available for UFC and the LD-DST (Elamin et al, 2008; Nieman et al, 2008). Furthermore, the test's usefulness in diagnosing

BOX 65-5 Pharmaceuticals That Affect Testing for Cushing Syndrome

DRUGS THAT ACCELERATE DEXAMETHASONE METABOLISM BY INDUCTION OF CYP3A4

Phenobarbital
Phenytoin
Carbamazepine
Primidone
Rifampin
Rifapentine
Ethosuximide
Pioglitazone

DRUGS THAT IMPAIR DEXAMETHASONE METABOLISM BY INHIBITION OF CYP3A4

Aprepitant, fosaprepitant
Itraconazole
Ritonavir
Fluoxetine
Diltiazem
Cimetidine

DRUGS THAT INCREASE CORTISOL-BINDING GLOBULIN AND MAY FALSELY ELEVATE CORTISOL RESULTS

Estrogens
Mitotane

DRUGS THAT INCREASE URINE FREE CORTISOL RESULTS

Carbamazepine
Fenofibrate (increase if measured by high-performance liquid chromatography)
Some synthetic glucocorticoids (immunoassays)
Drugs that inhibit 11β-hydroxysteroid dehydrogenase type 2 (licorice, carbenoxolone)

This should not be considered a complete list of potential drug interactions. Data regarding CYP3A4 obtained from <http://medicine.iupui.edu/flockhart/table.htm>.

From Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab* 2008;93:1526–40.

subclinical Cushing syndrome has been questioned (Nunes et al, 2009).

Unacceptably high false-positive rates may occur in patients with depression, altered sleep patterns, and chronic illness, because normal circadian variation in cortisol levels can be altered in these individuals. Tobacco use can affect salivary cortisol levels and should be avoided on the day of testing (Nieman et al, 2008). Some clinicians instruct patients to avoid oral food or liquid intake, brushing teeth, or undergoing stimulating activity within 30 minutes of salivary collection. Collection is rescheduled if the patient feels ill (Nunes et al, 2009). Some experts advise repeating salivary testing at least twice, regardless of the initial result (Nieman et al, 2008).

24-Hour Urinary Free Cortisol Evaluation. The UFC evaluation is a 24-hour direct measurement of free bioavailable cortisol. This test is an integrated measurement of cortisol secretion over a 24-hour period and does not depend on variables that influence corticosteroid-binding globulin levels (e.g., oral contraceptives) (Arnaldi et al, 2003). This study has been recommended as an initial test to screen patients with incidentalomas for Cushing syndrome (Orth, 1995); however, some recent evidence suggests that the study may not be sensitive enough to detect subtle glucocorticoid metabolism perturbations in patients with cortisol-secreting

adrenal lesions (Terzolo et al, 2005; Tsagarakis et al, 2006; Mitchell et al, 2007). Practice guidelines issued by the Endocrine Society in 2008 recommend that the dexamethasone suppression test or the late-night salivary cortisol test supplant the 24-hour UFC evaluation in initial metabolic screening of patients with incidentalomas (Nieman et al, 2008). Nevertheless, this test remains the test of choice in pregnant patients. In the second and third trimester, cutoff values twofold to threefold above the normal laboratory threshold must be used to account for the physiologic hormonal changes associated with pregnancy (Nieman et al, 2008).

As in all 24-hour urine collections, the patient is instructed to discard the morning's first voided urine and begin to collect all subsequent voided samples. The last sample that is collected is the first morning's void of the following day. Collection and analysis of two separate samples from each patient is advised. The test is most accurate in patients with a GFR greater than 60 mL/min because false-negative results may arise in patients with poor renal function (Nieman et al, 2008). Creatinine levels in the collection must be checked to verify completeness of the collection.

As for all tests, sensitivity and specificity of the UFC depend on the population that is being tested and the normal cutoff values that are selected. Normal cutoff values of approximately 50 μ g to 100 μ g per 24 hours of urine volume are usually used, but these vary depending on the laboratory where the test is performed and the assay used (Orth, 1995; Lin et al, 1997; Pecori Giraldi et al, 2007). Again, cutoff values in the second and third trimesters of pregnancy must be raised approximately threefold to account for physiologic changes. As stated previously, the sensitivity of UFC for patients proven to exhibit hypercortisolism secondary to an adrenal adenoma has been reported to be as low as 85% (Invitti et al, 1999), whereas the specificity of the test in a population of patients with suspected Cushing syndrome appears to be in the 90% range (Pecori Giraldi et al, 2007).

Testing for Aldosterone Hypersecretion

Hypersecretion of aldosterone by adrenal masses is extremely rare, with only approximately 1% of adrenal adenomas responsible for Conn syndrome (Young, 2000). Nevertheless, data demonstrate that nearly 5% of newly hypertensive patients may harbor an aldosterone-secreting adenoma (Rossi et al, 2006a). Indeed, testing of hypertensive patients with adrenal lesions for hyperaldosteronemia is clinically recommended. Testing of nonhypertensive patients, however, currently is not recommended. The section on **primary aldosteronism** describes the physiologic rationale for each test. In this section, we review the practical implications of evaluating adrenal incidentalomas for excess aldosterone secretion.

In the past, low serum potassium level has been used as a screening tool to assess for presence of aldosterone hypersecretion. Despite this prior teaching, contemporary series reveal that less than 40% of patients with hyperaldosteronism exhibit hypokalemia (Mulatero et al, 2004). Today the screening test of choice for Conn syndrome is the ratio of morning plasma aldosterone (ng/dL) to renin (ng/mL/hr). An ARR of 20 (some suggest 30) along with a concomitant aldosterone concentration above 15 ng/mL is indicative of Conn syndrome (Grumbach et al, 2003; Mulatero et al, 2004; Vierhapper, 2007; Young, 2007b). The concurrent elevated aldosterone level appears important for cases in which the ARR is elevated simply because of a low renin level. The test's characteristics have not been fully defined; however, sensitivities and specificities in the 90th percentile have been reported (Montori and Young, 2002; Young, 2007a).

Blood samples should be drawn between 8 AM and 10 AM, preferably with the patient in the sitting position. Note that this timing is also ideal for drawing the morning cortisol level for an LD-DST. Some experts believe that hypokalemia may result in false-positive results owing to physiologic aldosterone elevation, and therefore patients with low potassium levels should undergo repletion before testing (Young, 2007a). Potassium-sparing diuretics such as amiloride, and especially mineralocorticoid receptor blockers such as spironolactone, alter the RAAS and will affect test results.

β -Blockers — consider discontinuing for several weeks before testing

$$\frac{\text{Aldosterone} \leftrightarrow}{\text{Renin} \downarrow} = \text{ARR} \uparrow \text{ (possible false positive)}$$

ACE inhibitors — no need to discontinue before testing (see text)

$$\frac{\text{Aldosterone} \downarrow\downarrow}{\text{Renin} \uparrow} = \text{ARR} \downarrow \text{ (small chance of false negative)}$$

Calcium channel blockers — no need to discontinue before testing

$$\frac{\text{Aldosterone} \leftrightarrow}{\text{Renin} \leftrightarrow} = \text{ARR} \leftrightarrow$$

Figure 65-32. Effect of antihypertensives on screening for hyperaldosteronism. Potassium-sparing diuretics and mineralocorticoid receptor blockers are not included in the figure, because they greatly alter the renin-angiotensin-aldosterone axis and should be stopped at least 6 weeks before aldosterone-renin ratio (ARR) testing. The ARR must be interpreted in the context of the aldosterone and renin levels (see text). ACE, angiotensin-converting enzyme.

These agents should be stopped approximately 6 weeks before testing (Young, 2007a). Also, historically, there has been great concern about ARR reliability in patients who are on other antihypertensive medications. Indeed, until recently, cessation of all antihypertensive therapy was recommended for a minimum of several days before ARR testing. Data now suggest that this may be unnecessary. Figure 65-32 summarizes the effects of various antihypertensive agents on aldosterone and renin levels and on the ARR. The urologist must remember that patients on β -blockers who continue therapy through testing may show a false-positive rise in ARR. Interpretation in these cases should be unaffected because the concurrent aldosterone level remains within normal limits (Young, 2007a). Nevertheless, some experts recommend cessation of β -blockade before testing (Seifarth et al, 2002). ACE inhibitors and angiotensin receptor blockers (ARBs) can lower aldosterone levels while raising renin levels in normal individuals. The ARR in patients with and without hyperaldosteronism who are on these medications has been shown to fall. Cessation of ACE inhibitors and ARBs, however, is not required. First, aldosterone levels are unlikely to fall in patients with hypersecreting adrenal lesions in the setting of ACE inhibitor or ARB use, owing to the fact that this hypersecretion is independent of the RAAS. Second, undetectable renin levels can be used as an additional screen for the diagnosis of hyperaldosteronism. Indeed, renin levels rise in normal individuals, and undetectable renin concentrations should be used as a trigger for secondary (confirmatory) testing even in the setting of an ARR within the normal limits (Seifarth et al, 2002; Young, 2007a).

Confirmatory testing is mandatory in patients who test positive during the initial screen for Conn syndrome. Briefly, this testing involves a 72-hour oral sodium challenge followed by measurements of a 24-hour urinary aldosterone level. The intravenous saline infusion test and the fludrocortisone suppression tests are also used for confirmatory testing by some experts, although the latter test has fallen out of favor (Mulatero et al, 2004; Young, 2007a). We strongly recommend that the patient be referred to an experienced endocrinologist at this point in his or her care. Once hyperaldosteronism is confirmed, further workup with adrenal vein sampling may be necessary. Please refer to the section on **primary aldosteronism** for further discussion.

Testing for Adrenal Sex Steroid Hypersecretion

Hypersecretion of adrenal sex steroids by adrenal masses, especially incidentalomas, is exceedingly rare. The most common adrenal mass that hypersecretes sex steroid is an adrenal carcinoma that concomitantly exhibits cortisol hypersecretion (Wajchenberg et al, 2000; Cordera et al, 2003). Tumors that exclusively hypersecrete androgens—testosterone and/or 17-ketosteroids—have been reported primarily in women. Approximately 50% of such lesions ultimately prove benign (Cordera et al, 2003; Moreno et al, 2004). Routine testing of incidentalomas for sex hormones is currently not recommended (Grumbach et al, 2003; Stanczyk, 2006; Young, 2007b).

Previously for patients with virilization, dexamethasone suppression testing was used to differentiate adrenal androgen excess from an ovarian androgen source; however, this approach has proven unreliable and has been largely replaced by radiographic imaging strategies (Derksen et al, 1994; Cordera et al, 2003).

Testing for Catecholamine Hypersecretion

Pheochromocytoma is found in approximately 5% of patients with adrenal incidentaloma. Therefore all patients, including those in whom metastatic disease is suspected, should undergo functional testing to rule out pheochromocytoma (Adler et al, 2007; Young, 2007b). The section on pheochromocytoma describes the physiologic rationale for each test. Here we discuss the practical details regarding testing.

Free fractionated plasma metanephrines and the 24-hour urinary fractionated metanephrine test constitute the mainstay for pheochromocytoma testing, given their superb sensitivity and suitable specificity. Indeed, the 2005 International Symposium on Pheochromocytoma concluded that one of these two tests should be used for initial diagnosis and screening for pheochromocytoma (Grossman et al, 2006; Pacak et al, 2007). Currently there is an ongoing debate regarding which one of these tests is superior (Young, 2007b; Eisenhofer et al, 2008).

Plasma Free Metanephrines. The measurement of plasma free (fractionated) metanephrines has gained popularity owing to ease of testing and excellent test characteristics. In a study of over 850 patients (214 with pheochromocytoma, 644 without pheochromocytoma), Lenders and colleagues (2002) concluded that the test is superior to all other methods for diagnosing and excluding pheochromocytoma. Investigators in this multicenter study showed that

the test affords nearly perfect sensitivity in cases of sporadic (99%) and familial (97%) pheochromocytoma. Specificity was reported to be 82% for sporadic and 96% for familial cases (Lenders et al, 2002). Indeed, the test's low specificity (reportedly as low as 77%) in patients older than 60 may lead to false-positive results. For this reason, some experts advise against first-line use of plasma free metanephrines in all patients with incidentalomas (Sawka et al, 2003; Young, 2007b). Nevertheless, supporters of the test contend that the true specificity of the test is closer to 92% and that insufficient evidence exists to prove superiority of urinary testing and to eliminate plasma free metanephrines from routine first-line use (Eisenhofer et al, 2008). Further arguments for and against use of plasma free metanephrines are summarized in Table 65-16.

Ideally, patients should not consume food or liquids after midnight before the study. Caffeinated beverages must be avoided especially (Lenders et al, 2002). Acetaminophen can produce a false-positive result owing to cross reactivity in the assay and should be stopped for at least 5 days before testing. Tricyclic antidepressants and phenoxybenzamine should also be stopped, because these have been shown to be responsible for false-positive results (Eisenhofer et al, 2003b). Usual antihypertensive therapy can be continued. Although β -blockade can potentially result in a false-positive test result, the current recommendation is to stop the medication only on repeat testing (Eisenhofer et al, 2003b). Ideally, the serum sample should be drawn with the patient in the supine position after at least 20 minutes of supine rest. Position is especially important if a positive result has been obtained and confirmatory testing is being performed (Grossman et al, 2006).

The upper limit of normal for the test is usually set at 0.61 nmol/L (112 ng/L) for normetanephrine and 0.31 nmol/L (61 ng/L) for metanephrine (Lenders et al, 2002; Eisenhofer et al, 2003a, 2003b; Pacak et al, 2007). Elevation beyond 2.2 nmol/L (400 ng/L) for normetanephrine and/or 1.2 nmol/L (236 ng/L) for metanephrine is substantial and is highly indicative of pheochromocytoma. Lesser elevation in plasma free metanephrine levels necessitates repeat testing (Eisenhofer et al, 2003b). No consensus exists regarding the best strategy for repeat testing; however, such strategies as repeating plasma free metanephrine under ideal conditions (i.e., supine for 20 minutes, off β -blockers, and so on), performing urinary fractionated metanephrine testing, evaluating for elevated chromogranin A levels, and subjecting the patient to clonidine suppression testing have all been suggested (Eisenhofer et al, 2003b; Lenders et al, 2005; Algeciras-Schimmich et al, 2008). At this point

TABLE 65-16 Relative Merits for and against Use of Plasma Free Metanephrines and Urinary Fractionated Metanephrines in Diagnosis of Pheochromocytoma

URINARY FRACTIONATED METANEPHRINES	PLASMA FREE METANEPHRINES
Well-established, widely available test.	Relatively new test with limited availability.
Urinary concentrations (200-2000 nmol) make analysis relatively easy.	Plasma concentrations (0.1-0.5 nmol) can make analysis difficult.
Easy for clinicians to implement with minimal expenditure of time and effort.	Blood collections require some time and effort by medical staff.
Twenty-four-hour collections can be inconvenient for patients.	Blood sampling relatively more convenient for patients.
Problems with reliability of incomplete timed urine collections.	Collection and handling of blood samples can be better regulated.
Difficult to control dietary and daily life influences on sympathoadrenal function.	Influences of diet and sympathoadrenal function more easily controlled.
In children, 24-hour collections are difficult to interpret without age-appropriate reference intervals.	In children, blood sampling may be stressful, but results are more easily interpreted without age-appropriate reference intervals.
Urine collections may be inappropriate in patients with renal failure.	Test is applicable in patients with renal failure.

From Grossman A, Pacak K, Sawka A, et al. Biochemical diagnosis and localization of pheochromocytoma: can we reach a consensus? *Ann N Y Acad Sci* 2006;1073:332-47.

in the patient's care, we strongly suggest involving an experienced endocrinologist.

24-Hour Urinary Fractionated Metanephrines. Some experts believe that 24-hour urinary fractionated metanephrines along with fractionated urinary catecholamine testing represent the best first-line test for pheochromocytoma (Perry et al, 2007; Young, 2007b). When measured with tandem mass spectrometry, and when an elevation in metanephrine (>1531 nmol/day), normetanephrine (>4001 nmol/day), or total metanephrines (>1563 nmol/day) level is considered as a positive result, sensitivity for detecting pheochromocytoma is reported to exceed 97% with a specificity of approximately 91%. Supporters contend that given this specificity, the test is superior to plasma free metanephrines because it avoids unnecessary false-positive results, especially in patient populations with relatively low pretest probabilities, such as those with incidentaloma (Sawka et al, 2003; Perry et al, 2007; Young, 2007a, 2007b). Nevertheless, critics argue that high specificity is achieved by raising reference limits, potentially compromising sensitivity (Eisenhofer et al, 2008). Furthermore, they point to results of Lenders and colleagues (2002) that showed urinary fractionated metanephrine to be inferior to plasma free metanephrines. Given strong opinions on both sides of the argument, the 2005 International Symposium on Pheochromocytoma failed to reach a consensus regarding the superiority of either test (Grossman et al, 2006; Pacak et al, 2007). Table 65-16 summarizes some additional arguments for and against urinary metanephrine testing.

As in all 24-hour urine collections, the patient is instructed to discard the morning's first voided urine and begin to collect all subsequent voided samples. The last sample that is collected is the first morning's void of the following day. Creatinine levels in the collection must be checked to verify completeness of the collection. The test is most accurate in patients with normal renal function. Tricyclic antidepressants and phenoxybenzamine should be stopped.

Follow-Up

A small percentage (approximately 2%), of metabolically silent adrenal incidentalomas are reported to show new metabolic activity during follow-up evaluation (Barzon et al, 2003). The most recent consensus statement by a panel of experts recommends

annual metabolic hormonal screening for the first 3 to 4 years after diagnosis, especially for masses that are 3 cm in diameter (Grumbach et al, 2003). Nevertheless, given a lack of strong data for this recommendation, the need for metabolic reevaluation of adrenal adenomas in patients who show no clinical signs of hormonal hypersecretion remains controversial (Barry et al, 1998; Bulow et al, 2006; Young, 2007b).

KEY POINTS: ASSESSMENT OF FUNCTION OF ADRENAL MASSES

- All adrenal incidentalomas demand a metabolic evaluation.
- Annual follow-up for 3 to 4 years is recommended for metabolically silent masses; however, de novo development of metabolic activity is rare.

Summary of Surgical Indications

Every urologist must clearly understand the indications for surgical intervention in patients with adrenal pathology. The decision-making and management algorithm for patients with adrenal incidentalomas is summarized in Figure 65-33. Box 65-6 also details the major surgical indications for resection of the adrenal gland. The table also includes existing recommendations for adrenal resection during renal surgery (Lane et al, 2009; O'Malley et al, 2009; Kutikov et al, 2011b; Weight et al, 2011).

CONCLUSIONS

The adrenal glands have long been recognized for their essential role in regulation of critical homeostatic functions. Indeed, these deceptively simple glands are central to myriad essential life-sustaining human functions. Despite the frequency of incidental adrenal lesions, relative to other essential organs, the adrenal glands are infrequent primary initiators of human diseases. Nonetheless, clinically significant abnormalities of the adrenal gland require

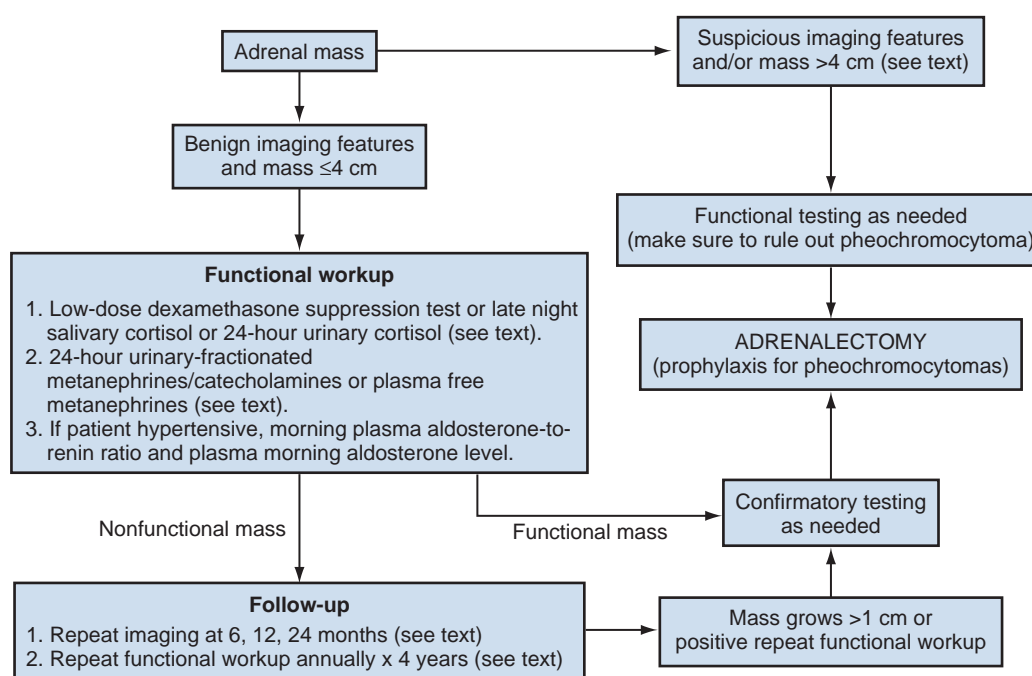

Figure 65-33. Management algorithm for newly diagnosed incidental adrenal mass.

BOX 65-6 Summary of Surgical Indications for Adrenalectomy

- Functional adrenal mass
 - Cortisol hypersecretion
 - Pheochromocytoma
 - Aldosterone hypersecretion
- Mass > 4 cm (see section on size and growth under [Imaging of Adrenal Masses](#)) with exception of myelolipoma
- Mass with imaging findings that are suggestive of malignancy (e.g., lipid poor, heterogeneous, irregular borders, infiltrates surrounding structures)
- Adrenal incidentaloma that grows more than 1 cm on follow-up imaging
- Extremely large and/or symptomatic myelolipoma (see section on [myelolipoma](#) under [Adrenal Lesions: Benign](#))
- Isolated adrenal metastasis (multidisciplinary decision making required)
- During renal surgery for renal cell carcinoma if:
 - Adrenal abnormal or not visualized because of large renal tumor size on imaging
 - Vein thrombus to level of adrenal vein
- Failed neurosurgical treatment of Cushing disease, necessitating bilateral adrenalectomy
- Select patients with ectopic adrenocorticotrophic hormone (ACTH) syndrome, requiring bilateral adrenalectomy
- ACTH-independent macronodular adrenal hyperplasia (AIMAH)
- Primary pigmented nodular adrenocortical disease (PPNAD)

a systematic multidisciplinary approach. With the urologist's advanced minimally invasive surgical skills, his or her comfort with both retroperitoneal anatomy and surgical approaches to retroperitoneal organs, and the close relationship between renal and adrenal pathophysiology, it is natural that the urologist participate in the evaluation of adrenal disorders and provide primary surgical management for these patients.

Future of Adrenal Surgery

Surgery of the adrenal gland is usually performed to control endocrine derangement after failed medical management or to treat malignancies. The first open adrenal surgery was performed in the late 19th century, and over the last century various operative techniques and surgical approaches had been developed and refined. The late 20th and early 21st centuries ushered the entrance of minimally invasive techniques for surgery of the adrenal gland. Although minimally invasive techniques have largely supplanted the open approach, the essential surgical principles of adrenal surgery remain unchanged and the open approach is still vital in the management of large, invasive adrenal carcinoma. Moreover, all urologic surgeons must be familiar with open techniques in the event that emergent open conversion is necessary.

The evolution of adrenal surgery is far from over and the future remains exciting. Virtual reality, computer simulation, and three- or four-dimensional reconstruction techniques, with their incorporation into existing robotic platforms, promise to push adrenal surgery to greater heights. In addition, minimally invasive nonsurgical approaches such as percutaneous ablative techniques may obviate not only scars but also the skills of the surgeon. Nevertheless, it is important that the urologist remain in the treatment team, either as a direct practitioner of the technique or in direct consultation guiding therapy.

EVOLUTION OF ADRENAL SURGERY

The early history of adrenal surgery is obscure because of the confusing nomenclature, the rarity of adrenal neoplasms, the lack of accurate diagnosis, and the ignorance of hormonal presentations associated with adrenal disorders. Indeed, the commonly used term *hypernephroma* was first proposed by Grawitz (1883), who erroneously believed that these neoplasms arose from adrenocortical tissue within the kidney.

Knowsly Thornton was credited with performing the first successful adrenal surgery in 1889 on a 36-year-old hirsute woman

with a large abdominal mass (Thornton, 1890). Although Thornton was unaware of the adrenal origin of the patient's tumor, a 20-pound left adrenal malignant tumor was resected en bloc with her left kidney. Despite a stormy postoperative recovery complicated by subphrenic abscesses, she survived 2 years before tumor recurrence. Sargent performed the first planned adrenalectomy in 1914 for a large adrenal adenoma. The first adrenalectomy was performed via a T-shaped subcostal incision, and most of these early adrenal surgeries employed incisions used for renal surgeries. Consequently, these incisions were usually too low for optimal access to the adrenal gland. Therefore surgeons began to site their incisions progressively higher, usually involving resection of the 11th or 12th ribs. In 1927, Charles Mayo performed the first flank adrenalectomy for a tumor from a retroperitoneal nerve, which was subsequently found to be a pheochromocytoma (Mayo, 1927). In 1932, Broster utilized a transpleural, transdiaphragmatic approach through a long, posterior intercostal incision, providing excellent access for adrenalectomy (Broster et al, 1932).

The anterior approach permitted a full exploration of the abdominal cavity and is helpful in surgeries involving large tumors but has its associated disadvantages owing to entry into the peritoneum. Lateral or flank incisions provide excellent access, but bilateral pathology such as Cushing syndrome caused by adrenal hyperplasia requires patient repositioning to access the contralateral side. Young described a "hockey stick" posterior approach in 1936 to access both adrenal glands simultaneously (Young, 1936). Although excellent for resecting smaller bilateral tumors, surgical access was difficult for larger lesions. The thoracoabdominal incision for large retroperitoneal masses was first described by Chute and colleagues (1949).

The year 1991 marked the beginning of the era of minimally invasive adrenal surgery when Gagner performed the first laparoscopic transperitoneal adrenalectomy (Gagner et al, 1992). In 1992 Gaur developed the first device for balloon dilation of the retroperitoneum (Gaur, 1992), and in 1995 Mercan reported the first case of retroperitoneoscopic adrenalectomy (Mercan et al, 1995). The

first robot-assisted laparoscopic adrenalectomies were reported by [Piazza and coworkers \(1999\)](#) and [Hubens and associates \(1999\)](#). In recent years, several techniques such as laparoendoscopic single-site (LESS) adrenalectomy and natural orifice transluminal endoscopic surgery (NOTES)-assisted laparoscopic adrenalectomy have moved to the forefront of the quest for smaller incisions or even “scarless” adrenal surgery.

SURGICAL ANATOMY

The adrenal glands are paired retroperitoneal organs situated within the Gerota fascia, residing on the superomedial aspect of each kidney. The adrenal cortex can be readily differentiated from the surrounding adipose tissue by its characteristic bright chrome yellow color with a finely granular surface and firm consistency.

The right adrenal gland is pyramidal in shape and is usually more cephalad than the left. It is bordered by the bare area of the right lobe of the liver anteriorly, the vena cava medially, the duodenum anteromedially, the diaphragm and pleura posteriorly, and the upper pole of right kidney inferiorly ([Fig. 66-1](#)). Unlike the left adrenal gland, the right is often fixed in its position and does not move down when the kidney is retracted downward. The right adrenal gland derives its arterial supply through the superior, middle, and inferior adrenal arteries from the inferior phrenic artery, the abdominal aorta, and the renal artery, respectively. The right adrenal vein takes a short (1-cm) transverse route at an angle of 45 degrees to empty into the posterior segment of the inferior vena cava and is usually not exposed until the adrenal gland is mobilized. **Consequently, meticulous dissection of the right adrenal vein is essential to avoid nicking the inferior vena cava.** The right inferior phrenic vein and aberrant smaller veins that are found in 5% to 10% of right adrenal glands may drain into the right hepatic or renal vein. These veins should be recognized intraoperatively to avoid accidental ligation of the right renal vein ([Fig. 66-2](#)).

The left adrenal gland is crescentic in shape and is bordered by the abdominal aorta medially, the cardiac part of the stomach and the body of the pancreas anteriorly, the spleen superiorly, the kidney inferiorly, and the diaphragm and pleura posteriorly. The arterial supply of the left adrenal gland is identical to its right counterpart. The left adrenal vein takes a longer course of 2 to 3 cm, passing downward from the lower medial aspect of the gland, receiving the left inferior phrenic vein before draining into the left renal vein. Occasionally, the left adrenal vein empties into the left inferior phrenic vein before entering the left renal vein or courses over the aorta to enter the inferior vena cava directly. The longer course of the left adrenal vein facilitates venous control during left adrenalectomy.

The lymphatic drainage from the adrenal glands empties into the lateral aortic lymph node chain extending from the diaphragm

to the ipsilateral renal artery and may end in the thoracic duct or the posterior mediastinal nodes after piercing the crura of the diaphragm.

CLINICAL INDICATIONS FOR ADRENALECTOMY

In general, adrenalectomy is indicated in functional adrenal masses or suspected adrenal malignancy, either primary adrenal cortical carcinoma or solitary metastasis from nonadrenal sources, the most common being lungs, breasts, kidneys, and skin (melanomas). The indications for adrenalectomy are summarized in [Box 66-1](#).

The increased use of abdominal imaging such as ultrasonography or computed tomography (CT) has led to increased incidence

BOX 66-1 Indications for Adrenalectomy

FUNCTIONAL ADRENAL TUMORS

Aldosterone-secreting adenomas (Conn syndrome)
Cortisol-secreting adenomas (Cushing syndrome)
Pituitary-dependent Cushing disease unsuccessfully managed by transsphenoidal surgery
Bilateral adrenal hyperplasia
Pheochromocytomas
Adrenal androgens/estrogen-producing tumors causing virilization/feminization

NONFUNCTIONAL ADRENAL TUMORS

Histologically confirmed adrenal cortical carcinoma
Symptomatic adrenal masses such as cysts, myelolipomas
Incidentally discovered adrenal tumors (adrenal incidentalomas)
Size criteria:

- Incidentaloma ≥ 6 cm
- Incidentaloma between 4 and 6 cm and enlarging on serial imaging
- Incidentaloma < 4 cm that is rapidly enlarging (> 1 cm in 1 year)

Hounsfield criteria:

- > 10 HU in an unenhanced CT scan
- Enhancement washout of $< 50\%$ and delayed attenuation of > 35 HU

Solitary adrenal metastasis from nonadrenal primary

CT, computed tomography; HU, Hounsfield units.

Figure 66-1. Regional anatomy of adrenal glands.

Figure 66-2. Vascular supply of adrenal glands.

of incidental adrenal masses. These adrenal “incidentalomas,” defined as any adrenal mass 1 cm or greater in diameter detected on radiologic imaging performed for indications other than primary adrenal disease, are reported in up to 4% of CT scans of the abdomen, with incidence increasing with age (Young, 2007). The size of an incidentaloma is a major determinant for surgical excision. Twenty-five percent of adrenal lesions greater than 6 cm are adrenal cortical carcinomas, and these larger lesions should be resected (NIH state-of-the-science statement, 2002). Risk of malignancy in lesions less than 4 cm is 2% and, if deemed low risk by imaging criteria, these lesions could be monitored. Approximately 6% of adrenal lesions between 4 and 6 cm are malignant, and surgical resection can be considered in appropriate individuals. Increase in lesion size of greater than 1 cm in 1 year is another consideration for adrenalectomy (National Comprehensive Cancer Network, 2014).

INDICATIONS AND CONTRAINDICATIONS FOR LAPAROSCOPIC ADRENALECTOMY

Over the last decade, there has been a slow paradigm shift from open adrenalectomy toward laparoscopic adrenalectomy for most adrenal lesions. There is a growing body of evidence from literature published by major laparoscopic centers around the world to indicate that laparoscopic adrenalectomy is replacing open adrenalectomy as the standard of care for surgical management of most adrenal lesions. The indications for laparoscopic adrenalectomy are summarized in Box 66-2.

Contraindications to laparoscopic adrenalectomy would be indications for open adrenalectomy (see Box 66-2). Although the current indications for open adrenalectomy are few, the choice of open approach over laparoscopic approach is dictated by the sur-

geon’s experience and expertise. A recent review of the Nationwide Inpatient Sample reported that in the United States, during the period of 1998 to 2006, the majority of adrenalectomies (83%) were still performed using the open approach, which occurred mainly in smaller nonteaching hospitals with an annual case volume of fewer than six cases per year (Murphy et al, 2010).

Absolute contraindications to adrenalectomy would include extensive metastatic disease, uncorrected coagulopathy, and severe cardiopulmonary disease that precludes anesthesia.

Past Surgical and Medical History

Previous abdominal surgeries may lead to intra-abdominal adhesions and scarring, which may render the laparoscopic approach difficult if not impossible. Siddiqui and coworkers (2010) reported an overall adhesiolysis rate of about 23% after any previous abdominal surgeries. However, this problem may be circumvented by modifying the laparoscopic approach according to the patient’s past surgical history. A retroperitoneal laparoscopic approach may be ideal in a patient with history of transperitoneal surgery while a transperitoneal laparoscopic approach may be the approach of choice in a patient with a previous flank, retroperitoneal surgery. Furthermore, Gill and colleagues (2001) have demonstrated the feasibility of a transthoracic laparoscopic approach that involves entering the thoracic cavity thoracoscopically and incising the diaphragm to approach the adrenal superiorly.

Conventionally, laparoscopic surgeries required the establishment of pneumoperitoneum that may lead to hemodynamic, metabolic, and neurologic adverse effects in patients with significant cardiopulmonary and neurologic diseases. Contraindications to establishment of pneumoperitoneum include patients with severe cardiac insufficiency, advanced chronic obstructive bronchitis, renal function insufficiency, acute glaucoma, recurrent spontaneous pneumothorax, vascular endocranial malformation, and hypertensive retinopathy. Giraudo and associates (2009) have described a gasless technique that made it possible for these patients to undergo laparoscopic adrenalectomy instead of the open approach.

Tumor Size

Large tumor size is considered a relative contraindication to laparoscopic adrenalectomy. A larger size increases the chance that the tumor is malignant and also distorts the regional anatomy, making laparoscopic resection more difficult. Although most laparoscopic surgeons are comfortable with tumor sizes of up to 6 to 7 cm, there is no clear upper limit to the size at which the laparoscopic approach would be contraindicated. However, available literature seems to suggest an arbitrary upper limit of about 10 to 12 cm in diameter (Henry et al, 2002; MacGillivray et al, 2002; Zografos et al, 2010). The studies by MacGillivray and colleagues (2002) and Zografos and coworkers (2010) showed no difference in short-term morbidity in patients with larger tumor sizes (≥ 6 to 8 cm) compared to those with smaller tumors. A point to note is that CT can underestimate the size of adrenal tumors by as much as 12% to 23% compared with actual size determined by pathologic examination (Lau et al, 1999).

In contrast, Hobart and colleagues (2000) noted increased operative time, blood loss, complication rates, and open conversion rates in larger tumors removed laparoscopically (mean 8 cm vs. 2.2 cm). However, they reported that operative time, blood loss, hospital stay, and complication rates were lower with laparoscopic adrenalectomy compared to open surgery. More recently, Bittner and coworkers (2013) reported similar findings in favor of laparoscopic adrenalectomy over the open approach in a larger cohort.

Conversion to open surgery has been found to be associated with size of tumor and infiltrative adrenal cortical carcinoma. MacGillivray and colleagues (2002) concluded that preoperative CT scanning can identify those infiltrative tumors that are likely to be invasive carcinoma. Bittner and coworkers (2013) found that a tumor size of greater than 8 cm increases the risk of open conversion during laparoscopic adrenalectomy significantly (by 14 times).

BOX 66-2 Indications and Contraindications for Laparoscopic Adrenalectomy

INDICATIONS

Functional adrenal tumors

- Aldosterone-secreting adenoma
- Cortisol-secreting adenoma
- Bilateral adrenal hyperplasia
- Pheochromocytoma

Symptomatic benign adrenal cyst or myelolipoma

Small incidentaloma without clinical or radiologic evidence of malignancy and local invasion

CONTRAINDICATIONS

Relative

Large tumor (>6 cm)

Localized adrenal cortical carcinoma without adrenal vein or vena caval involvement

Morbid obesity

Malignant pheochromocytoma

Virilizing adrenal tumor (70%-80% of these tumors are actually functional adrenal cortical carcinoma)

Significant abdominal adhesion

History of recurrent pyelonephritis

Pregnancy

Absolute

Local recurrence of a previously resected adrenal mass

Invasive adrenal cortical carcinoma with evidence of invasion of neighboring organs or renal artery or vena caval involvement

Severe cardiopulmonary disease

BOX 66-3 Oncologic Principles of Resection for Adrenal Cortical Carcinoma

1. No touch technique
2. Preservation of the intact peritoneum on the anterior surface of the adrenal gland if no evidence of invasion through the overlying peritoneal layer
3. En bloc resection of tumor with a wide margin of surrounding benign tissue outside the tumor capsule
4. Strict preservation of an intact tumor capsule
5. Exclusion of the remainder of the peritoneal cavity as much as possible using barriers such as laparotomy pads, plastic barriers, or drapes
6. Minimizing of bleeding and fluid spillage into the peritoneal cavity
7. Change of gloves, gowns, and instruments after removal of the tumor and prior to closure of the abdomen.

Modified from Porpiglia F, Miller BS, Manfredi M, et al. A debate on laparoscopic versus open adrenalectomy for adrenocortical carcinoma. *Horm Cancer* 2011;2:372–7.

Adrenal Cortical Carcinoma

Laparoscopic adrenalectomy in adrenal cortical carcinoma is currently controversial. In a consensus statement from the Third International Adrenal Cancer Symposium, the oncologic principles for resection of adrenal cortical carcinoma were outlined as summarized in [Box 66-3](#) ([Porpiglia et al, 2011](#)). Strict adherence to these principles of resection is difficult during laparoscopic adrenalectomy and thus the open approach seems to be the technique of choice. The thin tumor capsule is prone to rupture during inevitable manipulation of tumor during dissection, resulting in tumor spillage and subsequent recurrence. Furthermore, en bloc dissection of the retroperitoneal fat around the tumor is more difficult using laparoscopic techniques. However, this is often necessary because microscopic tumor extension cannot be accurately identified pre- and intraoperatively and there are currently no effective adjuvant treatments if margins are positive.

To determine whether the surgical approach for adrenal cortical carcinoma is a risk factor for peritoneal carcinomatosis, [Leboulleux and colleagues \(2010\)](#) reviewed 64 patients with stages I to IV disease with a median follow-up of 35 months. Of these, 58 patients underwent open adrenalectomy and 6 underwent laparoscopic adrenalectomy. The 4-year rate of peritoneal carcinomatosis was 67% for laparoscopic adrenalectomy and 27% for the open approach, with surgical approach being identified as the only risk factor. Data reported from the MD Anderson Cancer Center in 2005 showed similar outcomes with regard to increased risk of peritoneal carcinomatosis after laparoscopic adrenalectomy ([Gonzalez et al, 2005](#)). [Miller and coworkers \(2010\)](#) demonstrated in a retrospective review that 17 patients who underwent laparoscopic adrenalectomy showed significantly faster local recurrence time and higher rates of tumor spillage and positive surgical margins when compared to 71 patients who underwent open adrenalectomy. Although the local and overall recurrence rates were similar in both groups, they concluded that laparoscopic resection should not be attempted in patients with tumors suspicious for or known to be adrenal cortical carcinoma.

In contrast, a study from the German Adrenocortical Carcinoma Registry Group comparing 117 patients undergoing open adrenalectomy and 35 patients undergoing laparoscopic adrenalectomy for stages I to III adrenal cortical carcinoma showed no significant difference in disease-specific and recurrence-free survivals, tumor capsule violation, and peritoneal carcinomatosis ([Brix et al, 2010](#)). However, this study was limited by having more patients with higher stage tumors in the open adrenalectomy group, short follow-up duration, and incomplete data, especially on resection

margin status. [Porpiglia and colleagues \(2010\)](#) concluded that open and laparoscopic adrenalectomy may be comparable in terms of recurrence-free survival for patients with stages I and II adrenal cortical carcinoma based on a retrospective analysis of 43 patients. A major limitation of this study was that patients who had macroscopically incomplete resection, tumor capsule violation, open conversion from laparoscopic approach, and microscopic periadrenal fat invasion on postoperative pathologic examination were excluded, introducing significant selection bias. In addition, the follow-up period of less than 1 year in some patients is relatively short for diagnosis of tumor recurrence.

There is currently no consensus opinion on the role of laparoscopic adrenalectomy in adrenal cortical carcinoma. The 2014 National Comprehensive Cancer Network (NCCN) guidelines recommended open adrenalectomy for adrenal cortical carcinoma ([NCCN, 2014](#)). The Third International Adrenal Cancer Symposium ([Porpiglia et al, 2011](#)) suggested that **laparoscopic adrenalectomy can be considered in small incidentalomas, indeterminate large incidentalomas without necrosis or evidence of invasion, and small adrenal cortical carcinoma only if surgery is limited to referral centers with at least 20 cases of laparoscopic adrenalectomy per year and oncologic principles are adhered to, with avoidance of tumor violation and extraction of tumor without fragmentation.**

PREOPERATIVE AND PERIOPERATIVE MANAGEMENT

In general, preoperative management for adrenal surgery is similar to most general abdominal surgeries. Preoperative anesthetic consultation and optimization of the patient's medical conditions are essential. Mechanical bowel preparation and orogastric/nasogastric tube insertion are recommended in open or laparoscopic transperitoneal surgery and are optional for retroperitoneal approaches. The placement of a urinary catheter prior to surgery is helpful to measure urine output and to decompress the bladder. For functional tumors, special considerations are required ([Box 66-4](#)).

Pheochromocytoma

Excessive secretion of catecholamines from chromaffin tissue may result in tachycardia, diaphoresis, headache, hypertension, cardiac arrhythmias, left ventricular dysfunction, and impaired glucose tolerance. Preoperative cardiac workup, including electrocardiography and echocardiography, and assessment of hypertension-induced end-organ dysfunction are indicated. Preoperative sympatholytic therapy with α -adrenergic blockers for at least 2 weeks before surgery helps in both hemodynamic and glucose control and should be continued until the day of surgery. Phenoxybenzamine is time proven to be safe and effective but has its associated problems. Its nonselective nature may lead to tachycardia and β -adrenergic blockade may be necessary. Being an irreversible non-competitive α -adrenergic blocker, prolonged hypotension in the immediate postoperative period and central nervous system effects such as somnolence may be expected. Newer selective and competitive α_1 -adrenergic blockers such as doxazosin, prazosin, and terazosin obviate the drug-induced need for β -blockade. **β -Adrenergic blockade, if needed, must be given with caution in patients with myocardial depression and started only after phenoxybenzamine therapy.**

Intraoperatively, hypertensive episodes should be anticipated and can be controlled with intravenous drugs with rapid onset and short half-life such as nitroprusside, phentolamine, nitroglycerin, and nicardipine. Temporary cessation of surgical manipulation of the pheochromocytoma may be necessary. Short-acting β -blockers such as labetalol and esmolol are also good choices. Aggressive fluid management with volume repletion is necessary after removal of pheochromocytoma because hypotension can occur as a result of sudden loss of tonic vasoconstriction.

Postoperatively, fluid administration and use of vasopressors such as phenylephrine, guided by invasive monitoring, are useful

BOX 66-4 Preparation of Patients for Adrenal Surgery**PRIMARY ALDOSTERONISM**

Magnesium and potassium repletion
 Normalization of intravascular fluid status
 Blood pressure control
 Stress dose of cortisol

CUSHING SYNDROME

Inhibition of glucocorticoid production with metyrapone when there is severe manifestation
 Control of diabetes
 Preoperative antibiotics
 Cardiopulmonary workup
 Operative steroid administration

INCIDENTALOMAS

Anesthetic preparation for pheochromocytoma; 5% have normal diagnostic studies
 Full endocrinology workup

ADRENAL CARCINOMA

Consent for adjacent organ removal
 Failure to identify vena cava involvement

PHEOCHROMOCYTOMA

Preoperative catecholamine blockade
 Consider β -blockers if necessary
 Volume expansion
 Anesthetic consultation

Modified from Vaughn ED. Complications of adrenal surgery. In: Taneja SS, Smith RB, Ehrlich RM, editors. *Complications of urologic surgery: prevention and management*. 3rd ed. Philadelphia: Saunders; 2001. p. 363.

to manage hypotension. Electrolyte abnormalities and hypoglycemia should be corrected. It is not uncommon for patients to remain hypertensive postoperatively, and antihypertensive management should be continued.

Conn Syndrome

Primary hyperaldosteronism can lead to electrolyte and acid-base disturbances such as hypokalemia, hypomagnesemia, and alkalosis; fluid depletion or retention; refractory hypertension; and cardiac dysfunction and arrhythmias. These issues should be resolved preoperatively. An aldosterone antagonist (spironolactone) should be started at least 1 to 2 weeks before surgery, especially in patients on long-term angiotensin-converting enzyme inhibitors (Winship et al, 1999). Correction of hypomagnesemia may be indicated in cases of refractory hypokalemia. Diuretics or fluid repletion should be tailored according to fluid status. If bilateral adrenal manipulation or resection is planned, a stress dose of cortisol should be considered preoperatively and continued for 24 hours.

Postoperatively, monitoring of electrolytes should be continued regularly because hypokalemia may persist for up to a week after surgery. Persistent hypertension requires pharmacologic treatment, and a temporary or permanent mineralocorticoid or glucocorticoid might be necessary in patients with bilateral adrenalectomy.

Cushing Syndrome

Hypercortisolism can lead to obesity, hypertension, diabetes, myopathy, hypokalemia, fluid retention, and cardiac dysfunction. Obesity is associated with obstructive sleep apnea and may result in airway

Figure 66-3. Surgical incision over 11th rib for flank adrenalectomy. The patient is in flexion, with the kidney rest deployed to maximally expose the right retroperitoneum.

and ventilatory problems during anesthesia. Myopathy and intestinal motility abnormalities can result in postoperative respiratory problems and aspiration pneumonia. Preoperative anesthetic and cardiopulmonary consultations should be sought. Preoperative optimization of fluid status, blood pressure, and glucose control and correction of electrolyte abnormalities are necessary. Use of spironolactone or inhibitors of steroid production such as mitotane and aminoglutethimide can be considered. Proton pump inhibitors and prokinetics such as metoclopramide can be considered to reduce risk of aspiration.

Postoperatively, patients must be monitored for respiratory depression. Epidural analgesia is recommended to minimize use of systemic opiate analgesia, which can lead to respiratory depression. Breathing exercises should be initiated early, and nonsteroidal analgesics can be considered. In patients with bilateral adrenalectomy, steroid replacement therapy should be initiated at the time of tumor resection and continued postoperatively. Cardiovascular instability and electrolyte abnormalities can occur and must be monitored.

OPEN ADRENALECTOMY

Open adrenalectomy can be broadly classified into transperitoneal and retroperitoneal approaches. Transperitoneal approaches include the anterior transabdominal and thoracoabdominal approaches, where the main advantages lie in excellent surgical exposure and better access to the hilum and great vessels, at the expense of higher risk of intra-abdominal organ injury and ileus. Retroperitoneal approaches include the flank and posterior lumbodorsal approaches, which result in a smaller operative field but are associated with less ileus and shorter hospitalization. In addition, the retroperitoneal approach is ideal for the morbidly obese patient in whom the abdominal panniculus will fall forward in a flank or prone position.

Flank Retroperitoneal Approach

Positioning. The patient is placed in the lateral decubitus position with the side with adrenal pathology up. The table is flexed at the level of the costal margin and a kidney rest is employed to maximize the distance between the costal margin and the iliac crest. An axillary roll is placed under the axilla with the arm closest to the table extended secured on an armboard and the upper arm slightly flexed at the elbow and placed on an elevated arm rest. The lower leg is flexed and the upper leg straight with pillows placed between them. All bony prominences are padded and the patient is secured to the operating table.

Incision. The course of the 11th rib is palpated and the incision is made along the rib as shown in Figure 66-3. The latissimus dorsi, external and internal oblique, and transversus abdominis muscles overlying the rib are divided until the anterior surface of the rib is exposed (Fig. 66-4).

11th Rib Excision. The anterior periosteum of the rib is scraped off using the periosteal elevator and the periosteum on the superior

Figure 66-4. Flank approach. Incision of muscle overlying 11th rib.

Figure 66-5. Flank approach. Excision of 11th rib.

and inferior aspects of the rib is visualized. The periosteum posterior to the rib can be scraped off in a similar manner with the periosteal elevator, taking care not to injure the neurovascular bundle that runs along the inferior aspect of the rib. After stripping the periosteum from the tip of the rib back to the paraspinal muscles, the 11th rib is cut with the rib cutter (Fig. 66-5). The rib stump is then smoothed with a rongeur and hemostasis is secured with the aid of cautery or bone wax. The neurovascular bundle is then freed athermally to avoid injury during subsequent dissection and closure (Fig. 66-6).

Creating the Retroperitoneal Space. The lumbodorsal fascia is entered and blunt dissection is used to dissect the peritoneum off the transverse fascia anteriorly. The muscles are divided and the plane between the Gerota fascia and the peritoneum is identified. This plane is then maximally developed with blunt dissection, reflecting the peritoneum anteromedially. A plane between the diaphragm and retroperitoneum is then developed, facilitating entry

Figure 66-6. Flank approach. Mobilization of the intercostal neurovascular bundle from the 11th rib. This is performed with a combination of blunt dissection with a Kittner dissector and sharp dissection with Metzenbaum scissors.

into the retroperitoneal space. Once the peritoneum is fully mobilized, the vena cava or aorta can be visualized. Further cephalad dissection will expose the adrenal gland and renal vein. Self-retaining retractors can now be placed with maximal exposure.

Dissection of Adrenal Gland. On the right side, dissection typically starts with the division of the peritoneal layer overlying the vena cava, along the medial border of the gland. The plane between the medial surface of the adrenal gland and the lateral vena cava is then bluntly dissected to expose the adrenal vein. The adrenal vein is then isolated with the aid of a right-angle instrument such as a Mixer forceps. The adrenal vein can then be ligated between silk ties or surgical clips. In the event of accidental avulsion of the vein resulting in hemorrhage from the vena cava, vascular control of the vena cava proximal and distal to the tear by vessel clamps or sponged forceps can be applied. The tear can then be repaired in the usual manner with 4-0 or 5-0 Prolene sutures (Ethicon, Cincinnati, OH).

The adrenal gland can now be dissected out starting with its superior attachments. Care must be taken to handle the friable adrenal gland via its surrounding adventitia to avoid tissue spillage, seeding, or autotransplantation. Actual arterial branches to the gland usually are not identified but can be safely cauterized during dissection of the gland. Clips or surgical ties should be employed if any vessels are identified. Inferomedial attachments to the kidney are then taken with sharp dissection or cautery and the freed adrenal gland is removed from the surgical field. Dissection of the left adrenal gland is similar except that the aorta is encountered and the left adrenal vein runs a longer course, typically originating from the renal vein.

Closure. After ensuring good hemostasis of the adrenal bed, the incision is closed in two layers with a running looped polydioxanone suture. The deeper layer consists of the transverse abdominal and internal oblique muscles and fascia and the outer layer consists of the external oblique muscle and fascia. Skin closure can be completed with staplers or absorbable/nonabsorbable sutures.

Posterior Lumbodorsal Approach

The posterior approach is the most direct route to the adrenal glands and no major muscles are divided, thus reducing dissection required to expose the adrenal glands. The prone position allows for ready access to both adrenal glands through two separate incisions. However, surgical exposure is limited and hence is usually reserved for smaller tumors or bilateral adrenal hyperplasia. In addition, access to the adrenal vein and great vessels is more difficult, which may be problematic in the event of excessive intraoperative bleeding. Finally, the prone position increases ventilatory difficulties. **This approach should not be used for large tumors or adrenal cortical carcinoma.**

Figure 66-7. Posterior approach—possible locations for lumbodorsal incisions.

Positioning. The patient is positioned in a prone position after intubation, with the operating table flexed at the level of the 12th rib. Pillows are placed under the abdomen and lower limbs and care is taken to avoid compression on the eyes in the prone position.

Incision and Rib Excision. Incisions can be made along the course of the 11th or 12th rib, or a hockey stick incision made about 5 cm lateral to the midline of the vertebral column, progressing downward and outward in a curvilinear fashion at the level of 10th rib, extending over or slightly below the 12th rib toward the iliac crest (Fig. 66-7). The technique of 12th rib excision on the right side is as follows. After the skin incision, division of the subcutaneous tissue and the latissimus dorsi and sacrospinalis muscles in layers exposes the 12th rib. The sacrospinalis is retracted medially and its attachment to the 12th rib is divided. Sequential division of the lumbodorsal fascia and then the posterior subcostal ligament releases the pleura from the 12th rib. The pleura dips below the 12th rib in the region of the costovertebral angle and may be perforated if the rib is elevated near the vertebral column. The 12th rib is then excised in a fashion similar to that described in the earlier section on the Flank Retroperitoneal Approach, with careful preservation of the neurovascular bundle. The 11th rib is then retracted upward to expose the retroperitoneum. If a bilateral procedure is undertaken, a Finochietto retractor can be used to assist in bilateral exposure (Fig. 66-8).

Dissection of Adrenal Gland. With division of the final hepatic attachments, the adrenal gland and the vena cava are visualized. The right adrenal vein is identified at its posterolateral origin and ligated between clips or ties. The arterial branches are then ligated and the adrenal gland is mobilized posteriorly away from the paraspinal muscles and dissected out, starting superiorly and progressing caudally.

Anterior Transabdominal Approach

The anterior transabdominal approach is indicated in cases of large or potentially malignant tumors for which adequate expo-

Figure 66-8. Bilateral posterior approach—anatomic relations to the adrenal gland as seen from behind.

Figure 66-9. Anterior approach. The transperitoneal approach may be attempted through a midline incision or subcostal incision. The subcostal incision can be extended into a full chevron for bilateral adrenalectomy or if a large unilateral tumor is encountered.

sure for extensive dissection is needed. It is also mandatory in cases of inferior vena caval or extensive nodal involvement. The anterior transabdominal approach may be attempted through a subcostal, chevron, or midline approach (Fig. 66-9). The subcostal or chevron incision provides better exposure of the superior and lateral aspects of the adrenal gland than the midline approach. The midline approach is generally reserved for cases in which an extra-adrenal pheochromocytoma is suspected along the great vessels or in the pelvis.

Left Adrenalectomy

Positioning and Incision. The patient is positioned supine with a body roll placed under the back at the level of the costal margin to accentuate the costal margin. For left adrenalectomy, the skin incision is made two fingerbreadths below the costal margin and

Figure 66-10. Anterior approach. Peritoneum lateral to the left colon is incised at the line of Toldt and extended cephalad to the splenocolic ligament and inferiorly.

Figure 66-11. Anterior approach. The left adrenal vein is dissected out and ligated.

extends medially to the midline. The external oblique, internal oblique, and transverse abdominal muscles are divided laterally and the rectus muscle and sheath are divided medially. The peritoneum is entered with sharp dissection and the falciform ligament is ligated.

Approach to Left Adrenal Gland. There are four different approaches to the left adrenal gland:

- Through the gastrocolic ligament
- Through the lienorenal ligament
- Through the transverse mesocolon
- Through the lesser omentum

The lienorenal ligament approach is described here. The line of Toldt is incised and the descending colon is mobilized medially. The splenic flexure is then taken down by dividing the splenocolic ligament (Fig. 66-10). Subsequent division of the lienorenal ligament and opening of the retroperitoneum along the inferior border of the pancreas will allow superior retraction of the spleen and pancreas with exposure of the left adrenal vein. The left adrenal vein is identified as it courses from the inferomedial border of the left adrenal gland into the left renal vein, and is ligated and divided (Fig. 66-11). The medial attachments to the aorta can now be taken either with monopolar diathermy on a long right-angle instrument or with a harmonic scalpel while applying gentle lateral traction on the gland. The lateral and inferior attachments to the kidney are taken by blunt and sharp dissection off the renal capsule, taking care to avoid the vasculature to the renal upper pole.

Closure. Closure of the incision is performed with a running No. 1 polydioxanone suture in two layers. The deep layer consists of the transverse abdominal muscle, transverse fascia, internal oblique muscle and fascia, and posterior rectus sheath. The superficial layer consists of the external oblique muscle and fascia and the anterior rectus sheath.

Right Adrenalectomy

After entering the peritoneum, the hepatic flexure is mobilized inferiorly and the liver is retracted superiorly. The Kocher maneuver is performed to mobilize the second part of the duodenum sharply, and the inferior vena cava is exposed (Fig. 66-12). The rest of the dissection is similar to that on the left side.

Figure 66-12. Kocher maneuver. The peritoneum is incised, and sharp dissection and blunt dissection are used to mobilize the second stage of the duodenum away from the renal hilum.

Thoracoabdominal Approach

The thoracoabdominal approach offers the best surgical exposure of the retroperitoneum, adrenal gland, and great vessels but may cause more morbidity, such as incisional pain, pulmonary morbidities, phrenic nerve injury during division of the diaphragm, and the need for a chest tube. This approach is generally reserved for large and invasive tumors with extensive involvement of surrounding structures or vena cava that cannot be safely removed.

Figure 66-13. Positioning for thoracoabdominal surgery. A body roll elevates the flank on the side of surgery, and the arm and shoulder are rotated away, supported by a sling.

Figure 66-14. Thoracoabdominal approach. Incision at the eighth intercostal space. The costal margin, external intercostal muscle and fascia, and anterior rectus sheath are divided.

via the anterior transabdominal approach. The thoracoabdominal approach is particularly useful in right-sided tumors since the liver and inferior vena cava can limit exposure whereas, on the left side, the spleen and pancreas can generally be elevated to provide adequate exposure.

Positioning. The patient is placed in a semioblique position at an angle of 45 degrees to the table with the operating side upward and the opposite side decubitus. A body roll or pillow is placed longitudinally along the hemithorax and flank to achieve and maintain this position. The ipsilateral arm is placed across the chest on a padded arm rest and the other arm is secured to an armboard (Fig. 66-13).

Incision and Dissection of Adrenal Gland. The incision is made along the eighth or ninth intercostal space extending from the posterior axillary line and curving over the costal margin into the abdomen (Fig. 66-14). The latissimus dorsi, serratus anterior, and intercostal muscles are divided. The costal cartilage is then divided with cautery and the incision is carried through the anterior and posterior rectus sheaths and the rectus abdominis muscle. The pleura is entered along the superior margin of the rib to avoid injury to the neurovascular bundle and the lung is packed away (Fig. 66-15). The diaphragm is divided in a circumferential fashion along its periphery. The surgeon must not cut directly to the center of the diaphragm because the phrenic nerve can be damaged. Marking sutures can be placed on either side of the divided diaphragm to aid alignment during closure. Once the diaphragm is divided, a Finochietto self-retaining retractor is placed. The rest of the dissection is similar to the previously described techniques. The relationship of the thoracoabdominal incision to the adrenal gland is illustrated in Figures 66-16 and 66-17.

Closure. A chest tube is placed and the diaphragm is closed with either running suture or interrupted figure-of-eight stitches with nonabsorbable sutures. In order to take tension off the diaphragmatic closure, the ribs should be reapproximated with several

Figure 66-15. Thoracoabdominal approach. The Finochietto retractor is placed to expose the anatomy. The lung visible in this view is packed away with laparotomy sponges.

Figure 66-16. Thoracoabdominal approach. Exposure of the adrenal.

interrupted No. 0 chromic sutures on blunt-tip liver needles around the superior border of the eighth rib and inferior border of the ninth rib. A No. 0 Prolene suture is placed through the cut costal cartilage to bring the costal margin together, followed by closure of the serratus anterior and latissimus dorsi muscles in two layers. The chest tube is then placed to a water seal and suction.

LAPAROSCOPIC ADRENALECTOMY

Transperitoneal Approach

Transperitoneal laparoscopic adrenalectomy can be performed with the patient in a supine or lateral position. In general, the

Figure 66-17. Demonstration of the route of surgical dissection via thoracoabdominal incision.

transperitoneal approach allows for a greater working space and a better visualization of the operative field and surrounding anatomic structures as compared to the retroperitoneal approach. The lateral transperitoneal approach allows for a greater working space as gravity aids in moving the bowels away from the surgical field. The supine approach permits bilateral adrenalectomy without repositioning the patient. However, more dissection and retraction of surrounding organs are generally needed with the supine approach, so it is usually reserved for bilateral adrenalectomy.

Transperitoneal Lateral Approach: Left Adrenalectomy

Positioning and Ports Placement. After general anesthesia, a urinary catheter and a nasogastric tube are inserted to decompress the bladder and the stomach. The patient can be positioned in either a full lateral position with the operating side upward or a modified lateral position angled at 45 to 60 degrees. The table can be straight or minimally flexed to increase the distance between the costal margins and the iliac crest. Care should be taken to avoid excessive flexion because this may lead to neuromuscular problems and decreased venous return. All bony prominences must be adequately padded and the patient strapped in position.

The initial 10-mm camera port can be inserted either with the open technique or with the aid of the Veress needle. After insufflation of the abdomen with CO₂, two or three other trocars are inserted under vision in the configuration shown in Figure 66-18. The 5-mm port at the anterior axillary line can be replaced with a 10- to 12-mm port for larger instruments and ease of specimen retrieval. The splenic flexure may need to be mobilized prior to insertion of this port. The optional fourth 2- or 5-mm port may be inserted to aid retraction in difficult dissection.

Mobilization of Colon and Spleen. The line of Toldt is incised and the colon is mobilized inferiorly (Fig. 66-19). The splenocolic and lienorenal ligaments are incised toward the diaphragm to the level of the gastric cardia, allowing for full medial rotation of the spleen away from the surgical field. Care should be taken to avoid injury to the stomach and diaphragm at this stage. A sudden loss of pneumoperitoneal pressure with increases in ventilation pressures may signify diaphragmatic perforation. With the spleen

Figure 66-18. Four-trocar configuration for left transperitoneal laparoscopic adrenalectomy.

Figure 66-19. Transperitoneal laparoscopic adrenalectomy. Incision of the line of Toldt and medial dissection of the left colon with cautery endoscopic scissors.

rotated away and the tail of the pancreas dissected off, the left adrenal gland will come into view. Occasionally, especially in patients with Cushing syndrome, dense retroperitoneal fat may obscure the adrenal gland. A laparoscopic ultrasound probe can be inserted through the 10- to 12-mm port for localization of the adrenal gland.

Ligation of Left Adrenal Vein and Mobilization of the Left Adrenal Gland. The left renal vein is identified and traced along its superior border to reach the point of entry of the left adrenal

Figure 66-20. Transperitoneal laparoscopic adrenalectomy. Exposure and dissection of the renal vein and left adrenal vein.

Figure 66-21. Transperitoneal laparoscopic adrenalectomy. Ligation and division of left adrenal vein.

vein (Fig. 66-20). The left adrenal vein is carefully isolated and ligated. It is advisable to place at least two clips on the stay side of the adrenal vein (Fig. 66-21). Care has to be taken to avoid any upper pole branch of the left renal artery, which may lie behind the adrenal vein. It is also important to recognize that the inferior phrenic vein may occasionally join the adrenal vein prior to its entry into the left renal vein. The adrenal arterial supply is divided either with cautery or a harmonic scalpel as the adrenal is dissected free (Figs. 66-22 and 66-23). Grasping on the adrenal gland should be avoided as the gland is fragile and tears easily, leading to increased intraoperative bleeding.

Closure. Once the adrenal gland is freed, it is placed in an endoscopic bag and removed via the 10- to 12-mm port (Fig. 66-24). Pneumoperitoneal pressure is reduced to 5 mm Hg and the surgical bed inspected for hemostasis. All port sites larger than 5 mm are closed in layers with fascial approximation and skin closure.

Figure 66-22. Transperitoneal laparoscopic adrenalectomy. Division of adrenal arterial supply and superomedial dissection with downward traction on the kidney.

Figure 66-23. Transperitoneal laparoscopic adrenalectomy. The adrenal gland is mobilized off the medial aspect of the kidney.

Transperitoneal Lateral Approach: Right Adrenalectomy

The port configuration for transperitoneal laparoscopic lateral right adrenalectomy is shown in Figure 66-25. An additional 2- or 5-mm port sited most superomedially is used for liver retraction. After creation of pneumoperitoneum, the first step is to mobilize the liver by dividing the triangular ligament laterally and inferiorly. The liver

Figure 66-24. Transperitoneal laparoscopic adrenalectomy. Placement of specimen in endoscopic extraction sac.

Figure 66-25. Four-trocar configuration for right transperitoneal laparoscopic adrenalectomy. Auxiliary site can be used for liver retraction.

is then retracted anterosuperiorly using the shaft of a 2- or 5-mm laparoscopic ratcheted locking forceps (Fig. 66-26). The lateral parietal peritoneum is grasped by the forceps, creating an assistant-free self-retaining retraction of the liver. A Kocher maneuver is then performed to mobilize the second part of the duodenum. This permits the visualization of the inferior vena cava and the right

Figure 66-26. A 2-mm trocar and locking grasping forceps can be used instead of a larger-caliber fan retractor to act as a self-retaining liver retractor. It is important that the trocar be placed just below the xiphoid process to ensure adequate retraction.

Figure 66-27. The LaparoTenser (L&T Lucini, Milan, Italy). (From Giraudo G, Pantuso G, Festa F, et al. Clinical role of gasless laparoscopic adrenalectomy. *Surg Laparosc Endosc Percutan Tech* 2009; 19:329–32.)

adrenal gland. The rest of the dissection is similar to that described on the left side.

Gasless Laparoscopic Transperitoneal Approach

Pneumoperitoneum is associated with several negative hemodynamic, metabolic, neurologic, and humoral effects. These include decreased venous return and cardiac output, elevated systemic arterial blood pressure, increased inspiratory and expiratory airway pressures and end-tidal carbon dioxide levels, decreased renal blood flow, and possible gas embolism. Pneumoperitoneum is thus contraindicated in certain groups of patients with preexisting cardiac, pulmonary, or neurologic diseases.

Giraudo and colleagues (2009) described their gasless laparoscopic adrenalectomy techniques using an abdominal wall lifting platform. The LaparoTenser (L&T Lucini, Milan, Italy) (Fig. 66-27) was used as an abdominal wall retractor, with two curved needles

(Aghi Pluriplan) placed in the subcutaneous tissue of the anterolateral abdominal wall. The intraperitoneal space was created by lifting of the abdominal wall, which eliminates the need for pneumoperitoneum. Three or four trocars are then inserted and dissection of the adrenal gland proceeds in a manner similar to that described earlier. The main suggested benefit of this technique is that it allows laparoscopic transperitoneal adrenalectomy to be performed as an alternative to open surgery in patients with contraindications to pneumoperitoneum.

Retroperitoneal Approach

Laparoscopic retroperitoneal adrenalectomy can be performed using either the prone or the lateral approach. The main advantage of the retroperitoneal approach is that entry into the peritoneum is avoided and thus complications such as visceral and bowel injuries are minimized. In the absence of pneumoperitoneum, hemodynamic and respiratory morbidities are also reduced. In addition, dense intraperitoneal adhesions arising from previous surgery or inflammation are averted by operating in the retroperitoneum. The main disadvantage of the retroperitoneal approach is the limited working space that makes dissection of large tumors difficult. Furthermore, because of the smaller skin surface area for port placement, the risk of improper port placement leading to colonic injury is increased (Liapis et al, 2008). Finally, the lack of anatomic landmarks and the abundant retroperitoneal adipose tissues may pose a significant challenge to surgeons inexperienced with the retroperitoneum.

The main advantage of the lateral approach over the posterior approach is the ease of conversion into the transperitoneal approach should difficulties be encountered. In contrast, the prone retroperitoneal approach allows for bilateral adrenalectomy without patient repositioning.

Retroperitoneal Lateral Adrenalectomy: Left Adrenalectomy

Positioning and Ports Placement. The patient is placed in the lateral position with the left side up with a kidney rest under the body and the operating table flexed to accentuate the left flank. A 1.5-cm incision is made near the tip of the 12th rib under the 11th rib. The underlying muscle and fasciae are divided with cautery until the lumbodorsal fascia is visible. This lumbodorsal fascia is then incised sharply and a finger is inserted to confirm access into the retroperitoneal space. The inner surface of the 12th or 11th rib should be palpable superiorly and the iliac crest felt inferiorly. Blunt finger dissection is used to create a plane between the psoas muscle and the posterior Gerota fascia by sweeping the kidney anteriorly and the peritoneum medially. This retroperitoneal space is then widened with a retroperitoneal dissection balloon inflated under direct vision by inserting the laparoscope into its transparent shaft. The balloon dissector is directed along the posterior abdominal wall in a cephalic direction. The psoas muscle is usually identifiable and this serves as a landmark for longitudinal orientation. A balloon-tip trocar is secured in position into this space and insufflation of the retroperitoneum is generated. A 5- or 10-mm trocar is placed at the angle of the paraspinal muscle and the origin of the 12th rib. Another 5- or 10-mm trocar is placed about two finger-breadths above the iliac crest near the anterior superior iliac spine (Fig. 66-28).

Ligation of Left Adrenal Vein and Mobilization of Left Adrenal Gland. By dissecting medially, the great vessels can be identified by their pulsation and their course parallel to the psoas. The renal hilum is then identified by the pulsation of the posteriorly situated renal artery. The superior border of the renal artery is dissected to expose the left adrenal vein as it courses anterior and cephalad to the renal artery toward the inferomedial border of the left adrenal gland (Fig. 66-29). The left adrenal vein is subsequently doubly clipped and ligated (Fig. 66-30). Small arterial branches arising from the aorta are ligated with cautery or a harmonic scalpel, mobilizing the medial border of the gland. The inferior and lateral borders of the gland are then mobilized in a similar manner from

Figure 66-28. Trocar placement for retroperitoneal laparoscopy. The dotted circles represent alternative sites for placement of a third port.

Figure 66-29. Retroperitoneal laparoscopic adrenalectomy. Dissection of the left adrenal vein by the retroperitoneal approach.

Figure 66-30. Retroperitoneal laparoscopic adrenalectomy. Ligation and division of left adrenal vein. The kidney is dissected away from the adrenal gland.

Figure 66-31. Anatomic view of right adrenal gland from laparoscopic retroperitoneal approach.

the upper pole of the left kidney. Finally, the anterior and superior borders of the gland are freed. The inferior phrenic vein may course along the anteromedial border of the gland to join the left adrenal vein. If encountered, it should be clipped and ligated.

Closure. The specimen is placed in an endoscopic bag and extracted through a 10-mm port. After ensuring adequate hemostasis, the trocar sites are closed in the standard fashion as described earlier.

Retroperitoneal Lateral Adrenalectomy: Right Adrenalectomy

The right adrenalectomy is performed in a similar fashion, dissecting cephalad along the inferior vena cava to reach the renal hilum and right adrenal vein. The anatomic relationships of this approach are illustrated in [Figure 66-31](#).

ROBOT-ASSISTED ADRENALECTOMY

Currently, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) is the only commercially available platform for robotic surgery. Since the first robot-assisted adrenalectomy in 1999, many centers around the world have jumped onto the bandwagon of robot-assisted adrenalectomy. The main benefits of the robotic system over conventional laparoscopy lie in superior ergonomics, three-dimensional (3D) magnification of the operative field, tremor filtering, and enhanced degrees of freedom of the EndoWrist (Intuitive Surgical, Sunnyvale, CA) instruments. These advantages of the robotic platform render it ideal in handling the fragile adrenal gland in a deep narrow space surrounded by major vessels and viscera where injury may lead to catastrophic consequences.

Robot-Assisted Lateral Transperitoneal Adrenalectomy

After insertion of a nasogastric tube and urinary catheter, the patient is positioned in an oblique lateral position with the affected side elevated on a kidney rest at an angle of 30 to 45 degrees from the table. The bony prominences are padded and the patient is strapped securely onto the table. The table is then tilted in the opposite direction to achieve a supine position for port placement. A longitudinal 1.2-cm supraumbilical incision is made and pneumoperitoneum is established with a Veress needle. A 12-mm optical port is inserted for the camera. Two 8-mm robotic ports and a 12-mm assistant port are inserted under vision in the configuration shown in [Figure 66-32](#). For right adrenalectomy, an additional 5-mm port is inserted just inferior to the xiphoid process for liver retraction ([Fig. 66-33](#)). In general, the distance between the camera and each robotic port should be at least 8 cm to reduce instrument clashing internally and

Figure 66-32. Left robotic adrenalectomy trocar placement. A total of four ports are placed: one 12-mm camera port (●), one 12-mm assistant port (●), and the two 8-mm robotic arm ports (●). The distance between each port should be at least 8 cm.

Figure 66-33. Right robotic adrenalectomy trocar placement. A total of five ports are used: one 12-mm camera port (●), one 12-mm assistant port (●), two 8-mm robotic arm ports (●) are established, and to retract the liver, a 5-mm trocar (○) is placed with a retraction device.

robotic arms clashing externally. The table is now tilted so that the patient lies in a full lateral position with the affected side upward. To facilitate access to the upper areas of the retroperitoneum, the robot is docked at an angle at the head of the table as outlined in [Figure 66-34](#).

The dissection and mobilization of the adrenal gland are similar to the transperitoneal laparoscopic techniques described earlier.

HAND-ASSISTED SURGERY

Hand assistance during laparoscopic surgery introduces enhanced tactile sensation and greater degrees of freedom of movement as compared to laparoscopic instruments. This may result in easier dissection, added security in the event of bleeding complications, and a shorter learning curve. With the introduction of the robotic system, hand-assisted adrenalectomy may have fallen out of favor in recent years, with publications limited to case reports and small case series published in the early 2000s. Hand-assisted adrenalectomy may be indicated in bilateral adrenalectomy or with large adrenal tumors that may require a larger incision for extraction. There may also be a role for hand-assisted surgery as an alternative to open conversion should laparoscopic dissection prove difficult or for bleeding complications.

Figure 66-34. Surgical room set-up for left robotic adrenalectomy. The slave unit of the robot is brought in over the patient's left shoulder as indicated in the diagram. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

LAPAROENDOSCOPIC SINGLE-SITE (LESS) ADRENALECTOMY

Laparoendoscopic single-site (LESS) surgery has recently been developed based on the principle that, with a smaller number of incisions and ports, enhancement of cosmesis and reduction of associated port site complications such as bleeding, organ injury, and incisional hernias can be attained. In general, all patients eligible for laparoscopic adrenalectomy can be considered for LESS depending on the surgeon's experience. However, because of the technical difficulties, LESS is most commonly performed for small (≤ 4 cm) and benign tumors.

Like conventional laparoscopic adrenalectomy, both transperitoneal and retroperitoneal approaches for LESS adrenalectomy have been described. Single multiluminal access ports are commercially available for LESS access. The umbilicus is the most common location for LESS access owing to the superior cosmetic results. However, the longer distance and the more tangential approach from the umbilicus to the adrenal gland render the surgery much more challenging. Alternative sites such as the subcostal margin or retroperitoneum have been described, albeit with less cosmetically appealing results. Moreover, the limited working space in the retroperitoneum makes the use of articulating and curved instruments more difficult when compared to the transperitoneal approach.

The inherent disadvantages of LESS surgery include reduced working space and loss of instrument triangulation leading to clashing, crossover, and paradoxical movement of instruments, as well as suboptimal approach to the adrenal gland and inadequate traction and countertraction. These disadvantages may translate into longer operative time and increased risk of tissue injuries and complications. Jeong and colleagues (2009) reported the first matched case-control study comparing 9 patients who underwent LESS adrenalectomy with 17 patients who underwent conventional laparoscopic adrenalectomy. Although the LESS adrenalectomy group required reduced postoperative analgesia, it was associated with a

non-statistically significant longer operative time and a case of bowel injury. Similarly, Shi and coworkers (2011) and Walz and associates (2010) reported a longer median operative time and lower analgesic requirements after LESS adrenalectomy compared to conventional adrenalectomy. Ishida and colleagues (2013) showed that tissue regrasping was more frequently observed (16.2 vs. 2.2 times) during LESS than in conventional adrenalectomy. Hu and colleagues (2013) summarized in their meta-analysis comparing LESS adrenalectomy and conventional laparoscopic adrenalectomy that, although LESS adrenalectomy is associated with a longer operative time, estimated blood loss and complications are similar. In addition, patients who underwent LESS adrenalectomy had a shorter hospital stay and reduced requirement for analgesia.

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY (NOTES)-ASSISTED LAPAROSCOPIC ADRENALECTOMY

Natural orifice transluminal endoscopic surgery (NOTES) utilizes natural orifices such as the mouth, urethra, vagina, or anus as entry points to perform intra-abdominal surgeries. In pure NOTES, access points are strictly limited to natural orifices. Hybrid-NOTES allows for additional incisions to be made, usually around the umbilicus, to facilitate surgery. Like LESS, the aims of NOTES are to improve cosmetic outcomes and convalescence and reduce hospitalization stay and analgesia requirements without compromising safety and efficacy.

Fritscher-Ravens and colleagues (2008) were among the first to attempt NOTES adrenalectomy. By using the transesophageal or transgastric route with the aid of endoscopic ultrasonography, they failed to remove the adrenal gland in all procedures in which it was attempted. Perretta and coworkers (2009) successfully performed bilateral adrenalectomy in two female pigs and two female

cadavers through a transvaginal retroperitoneal approach. The first report of hybrid-NOTES came from [Zou and colleagues \(2011\)](#), who presented their series of 11 female patients, with a median tumor size of 4.7 cm, who underwent transvaginal NOTES adrenalectomy. Injury to the spleen occurred in one patient necessitating open conversion and splenectomy. Median estimated blood loss was 80 mL. Almost all published literature describes NOTES adrenalectomy via the transvaginal route. Recently, [Eyraud and associates \(2013\)](#) described their transrectal robot-assisted NOTES techniques in a male cadaver. Despite these reports, NOTES adrenalectomy is still in its infancy and should only be considered as experimental.

PARTIAL ADRENALECTOMY

Unilateral adrenalectomy is often well tolerated and should be considered as the gold standard in the treatment of functioning or malignant adrenal tumors. Patients with bilateral adrenalectomy will require lifelong adrenal replacement therapy. Unfortunately, fixed daily dosing of steroids is associated with overdosing, which may result in osteoporosis, obesity, and Cushing syndrome, and with underdosing in times of stress. Life-threatening Addisonian crisis can occur. Patients after bilateral adrenalectomy continue to report poorer quality of life as compared to the general population ([Hawn et al, 2002](#); [van Aken et al, 2005](#)). Therefore partial adrenalectomy should be considered in patients with bilateral adrenal tumors, solitary adrenal gland, or familial syndromes such as von Hippel-Lindau disease, familial pheochromocytoma, and multiple endocrine neoplasia type IIA.

Partial adrenalectomy can be performed in any of the open, laparoscopic, or robot-assisted approaches described earlier. A major and important difference is that the adrenal gland is exposed but not mobilized. In open surgery, the tumor can usually be visualized or palpated. In laparoscopic or robotic surgery, lesions larger than 1 cm can usually be visualized. In any of these approaches, the use of intraoperative ultrasonography can help accurately localize and identify the tumor. Once the lesion is identified, only the affected portion is mobilized. The arterial supply of the adrenal gland forms a plexus circumferentially around the gland and can usually be removed without fear of devascularizing the adrenal cortex, and the gland will remain viable as long as it remains attached to the kidney or to an area of unmobilized connective tissue. The venous system drains into a central adrenal vein. Opinions are divided as to whether the main adrenal vein should be left intact during partial adrenalectomy. Some authors believe that removing the main adrenal vein will result in congested remnant adrenal tissues and difficult hemostasis, thus advocating its preservation ([Janetschek et al, 1998](#); [Imai et al, 1999](#)). In our experience and as concurred by other authors, the main adrenal vein can be removed as long as the remnant adrenal gland remains in situ without mobilization ([Walz et al, 1998](#); [Kaouk et al, 2002](#)). However, it would be prudent to preserve the main adrenal vein as long as it is safe and adequate margins can be obtained.

Partial adrenalectomy can be performed with either an endoscopic stapler ([Imai et al, 1999](#)), a harmonic scalpel ([Walz et al, 1998](#); [Sasagawa et al, 2000](#)), or cautery or cold endoscissors with clips or suture ligation. The use of the endoscissors allows for clear identification of the tumor plane and precise dissection but may lead to more bleeding. Finally, the cut surface can be sealed with fibrin glue or Surgicel (Ethicon, Cincinnati, OH) to prevent delayed bleeding. Frozen section is recommended if available; if not, intraoperative ultrasonography can be performed to confirm gross complete resection.

The amount of adrenal tissue that must be left behind after partial adrenalectomy to avoid insufficiency is not known. It has been suggested previously that at least 20% of the adrenal gland should be preserved ([Lee et al, 1996](#)). However, Lee and colleagues were unable to correlate the amount of adrenal tissue preserved with the presence of adrenal insufficiency.

OUTCOMES

Open versus Laparoscopic Adrenalectomy

There have been no prospective randomized controlled studies comparing open with laparoscopic adrenalectomy. It is highly doubtful that such a trial will ever be conducted because laparoscopic adrenalectomy is emerging as the gold standard technique for benign lesions and surgeons are pushing the boundaries for laparoscopic management of malignant tumors. Many large retrospective studies have consistently demonstrated superior outcomes of laparoscopic adrenalectomy over open surgery in terms of analgesia, hospital stay, blood loss, and complication rates. As surgeons gain more experience with laparoscopic surgeries, operative times have also decreased tremendously.

In an early meta-analysis of close to 100 studies comparing laparoscopic with open adrenalectomy, Brunt reported that, although the rate of bleeding complications was higher in laparoscopic (4.7%) than open (3.7%) adrenalectomy, total complication rates were lower in laparoscopic (10.9%) than open (25.2%) adrenalectomy ([Brunt, 2002](#)). Of note, open adrenalectomy was associated with significantly higher rates of associated organ injury and wound, pulmonary, cardiac, and infectious complications. There was also a higher non-statistically significant rate of mortality after open adrenalectomy (0.9% vs. 0.3%). Using the Veterans Affairs National Surgical Quality Improvement Program database to compare laparoscopic with open adrenalectomy, [Lee and colleagues \(2008\)](#) demonstrated that open procedures had increased operative times, transfusion requirements, reoperations, length of stay, and 30-day morbidity rates. Open adrenalectomy had also resulted in more pneumonia, unplanned intubation, unsuccessful ventilator wean, systemic sepsis, cardiac arrest, renal insufficiency, and wound infections. The 30-day morbidity rate was still higher even after adjusting for confounding factors. A Nationwide Inpatient Sample from the United States involving more than 40,000 patients who underwent adrenalectomy echoed similar findings of fewer complications and shorter length of stay in patients who underwent laparoscopic adrenalectomy over their open adrenalectomy counterparts ([Murphy et al, 2010](#)).

Most recently, using a contemporary cohort from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) data, [Elfenbein and colleagues \(2013\)](#) concluded that patients undergoing laparoscopic adrenalectomy had significantly lower postoperative morbidity and shorter length of stay than patients undergoing an open procedure after adjustment for patient- and procedure-related factors, including malignancy.

Laparoscopic Transperitoneal versus Retroperitoneal Approach

Multiple retrospective studies have been performed that seem to suggest an advantage in terms of lesser blood loss and shorter convalescence time of the retroperitoneal approach over the transperitoneal approach. In a meta-analysis of 22 eligible studies ([Constantinides et al, 2012](#)), the laparoscopic retroperitoneal approach was associated with a significantly shorter hospital stay when compared to the transperitoneal approach. The authors attributed this to the decrease in postoperative pain and ileus associated with the retroperitoneal approach because the peritoneum is not breached. There were no differences in duration of operation, blood loss, time to ambulation and oral intake, or complication rates between techniques. Another meta-analysis by [Chen and colleagues \(2013\)](#) identified nine eligible retrospective studies reporting that the retroperitoneal approach was associated with shorter operative time, less intraoperative blood loss, shorter hospital stay, and shorter time to first ambulation. There was no significant difference in open conversion rates, time to first oral intake, and major postoperative complication rates.

Three randomized prospective studies were carried out to compare these two approaches. [Fernández-Cruz and coworkers](#)

(1996) randomized 21 laparoscopic adrenalectomy patients into transperitoneal and retroperitoneal approaches. They showed that the transperitoneal approach resulted in a greater rise in the PaCO₂ level compared with the retroperitoneal approach at 30 minutes, together with a significant increase in mean arterial pressure. However, operation time, blood transfusion and analgesia requirements, hospital stay, return to normal activities, and complication rates were similar between the two approaches. The authors concluded that the retroperitoneal approach might be a better option in patients with previous abdominal surgery and preexisting cardiopulmonary diseases. In another prospective randomized trial by Rubinstein and colleagues (2005) in which all baseline patient and operative factors were matched, the only significant difference was a shorter convalescence time in the retroperitoneal group. All other parameters such as blood loss, operative time, analgesia requirements, open conversion, and complication rates were similar. Finally, a prospective randomized study involving a more contemporary cohort concurred with the previous findings that the transperitoneal approach was comparable to the retroperitoneal approach in terms of operative time, estimated blood loss, time to ambulation, hospital stay, and analgesic requirement but was associated with longer time to oral intake resumption and longer convalescence period (Mohammadi-Fallah et al, 2013).

Laparoscopic versus Robot-Assisted Adrenalectomy

As described previously, the robotic platform offers several advantages over conventional laparoscopy but current literature has yet to show conclusively that these advantages have translated into better clinical outcomes. The only prospective randomized study comparing robot-assisted with laparoscopic adrenalectomy was published in the early years of robot-assisted surgeries. Morino and coworkers (2004) randomized 20 consecutive patients with benign adrenal tumors to either traditional laparoscopic or robotic surgery. The robot-assisted approach was associated with a longer operative time and higher 30-day complication rate compared to the laparoscopic approach. In addition, cost analyses revealed that robotic procedures were more expensive than laparoscopic procedures. The authors concluded that laparoscopic adrenalectomy was superior to robot-assisted adrenalectomy in terms of feasibility, morbidity, and cost. In separate studies, Brunaud and colleagues concurred that patients' quality of life after robotic surgery was similar to that after laparoscopic surgery (Brunaud et al, 2004) but robotic surgery was 2.3 times more expensive (Brunaud et al, 2008).

Robot-assisted surgery requires the insertion of more trocars and docking of the robotic arms when compared to conventional laparoscopy, and these additional steps may lead to longer operative time (Morino et al, 2004; Wu et al, 2008; Pineda-Solís et al, 2013). Robotic surgery is highly dependent on the expertise of the assistant and the whole robotic team, including the scrub nurses. As robotic teams go beyond the initial learning curve of 10 to 20 cases, operative times have been shown to approach those clocked by the conventional laparoscopic approach (Brunaud et al, 2008; Agcaoglu et al, 2012a; Karabulut et al, 2012). Karabulut and colleagues went further to time each individual step of adrenalectomy and reported similar timings for each step of robotic and laparoscopic adrenalectomy, except for shorter hemostasis time in the robotic group (Karabulut et al, 2012).

Multiple studies have demonstrated that perioperative outcomes such as estimated blood loss, hospital stay, postoperative analgesia, and complication and mortality rates are similar between the two approaches. In fact, robot-assisted adrenalectomy may be preferred in certain circumstances. For tumors greater than 5 cm, Agcaoglu and associates (2012b) reported shorter operative time and hospital stay and lower open conversion and morbidity rates in robot-assisted as compared with conventional laparoscopy. In a separate study by Karabulut and colleagues (2012), the morbidity was 10% in the laparoscopic and 2% in the robotic group despite the fact that tumors in the robotic group were significantly larger. For obese patients with body mass index 30 kg/m² or greater, Aksoy and colleagues (2013) found no differences in operative time, estimated

blood loss, and hospital stay between robot-assisted and laparoscopic adrenalectomy. However, there was a lower conversion rate (0 vs. 5.2%) and a non-statistically significantly lower 30-day morbidity rate (4.8% vs. 7%, $P = .06$) in favor of the robotic approach (Aksoy et al, 2013).

COMPLICATIONS

Intraoperative

Box 66-5 summarizes the intraoperative complications that can occur. As expected, adrenal surgery, both open and laparoscopic, can involve injury to adjacent organs. Hemorrhage is a potentially catastrophic complication of adrenal surgery. Bleeding can result from injury to the adrenal vein, inferior vena cava, lumbar vein, or renal vein. These injuries are managed initially by application of direct pressure to the injury. Grasping a small injury with an Allis clamp (Scanlan International, St. Paul, MN) and closing it with suture or by placement of a vascular clamp for a larger vena cava injury may be curative. In the early days of laparoscopic adrenalectomy, open conversion was the typical consequence of vascular injury. However, with increasing experience with laparoscopic suturing techniques, these injuries are often managed as in the open surgery.

Ischemic injuries can occur as well. An upper pole renal artery branch can be divided inadvertently during dissection. If the branch is small and supplies a minimal portion of the kidney, it can be ignored. More substantial injuries may require a revascularization

BOX 66-5 Intraoperative Complications of Adrenal Surgery

ACCESS RELATED

Abdominal wall hemorrhage
Cutaneous nerve injury
Visceral injury by Veress needle or trocar

HEMORRHAGE

Inferior vena cava or aorta
Adrenal vein
Lumbar vein
Hepatic vein
Remnant adrenal gland after partial adrenalectomy

ISCHEMIA

Ligation of renal artery or vein
Ligation of superior mesenteric artery and vein

INJURY TO NEIGHBORING ORGANS AS A RESULT OF THERMAL ENERGY OR INCORRECT PLANE OF DISSECTION

Lung—pneumothorax
Pancreas
Liver
Spleen
Stomach and bowel, especially duodenum
Kidney

HEMODYNAMIC INSTABILITY

Pheochromocytoma

Modified from Vaughn ED. Complications of adrenal surgery. In: Taneja SS, Smith RB, Ehrlich RM, editors. Complications of urologic surgery: prevention and management. 3rd ed. Philadelphia: Saunders; 2001. p. 366.

attempt. If the patient has a large tumor there can be distortion of the regional anatomy, and inadvertent ligation of the superior mesenteric vein or artery is possible. This is a potentially fatal injury, and one must have a high index of suspicion to restore vascular supply to the bowel as soon as possible.

The adjacent organs can be injured during dissection of the adrenal gland. The liver can be injured during right adrenalectomy. Liver lacerations can be treated with argon beam coagulation and application of hemostatic agents such as methylcellulose. More serious injuries may require hemostatic sutures with a blunt-tip liver needle. The spleen can be injured during left adrenalectomy. As with hepatic injury, argon beam coagulation and hemostatic agents can be used to control bleeding. If this is not sufficient, splenorraphy can be attempted. If these measures are unsuccessful, splenectomy may be necessary. **It is important to remember to give pneumococcus, *Haemophilus influenzae* type B (Hib), and meningococcus vaccinations to these patients during postoperative care.**

The pancreas can be injured during surgery on either the right or left adrenal gland. If an injury to the tail of the pancreas occurs, distal pancreatectomy may be performed. If the injury is to the pancreatic duct, this may be repaired and surgical drains left. If there is uncertainty of pancreatic injury, leaving closed-suction surgical drains behind is advisable. Postoperative drainage high in triglycerides is indicative of pancreas injury. Management consists of bowel rest with parenteral nutrition. The administration of octreotide can decrease pancreatic secretions while the pancreas heals.

The proximity of the kidney to the adrenal gland can be a problem in cases of large adrenal cortical carcinomas. **It is imperative for all patients undergoing surgery for large adrenal masses to be counseled about the possibility of concurrent en bloc nephrectomy.**

During 11th-rib or higher flank adrenalectomy, it is not unusual for pleural injury to be incurred. These injuries can be repaired with a purse-string chromic suture and a red rubber catheter to water seal. Expulsion of air from the pleura followed by cinching of the purse-string suture usually repairs the defect. Postoperative chest radiography should be routinely performed after flank or thoracoabdominal nephrectomy. If a significant pneumothorax is present, a chest tube should be placed.

With pheochromocytoma, blood pressure fluctuations can be life threatening. The anesthesiologist typically manages high blood pressure with short-acting β -blockade, α -blockers, or nitroprusside. Arrhythmias are usually treated with β -blockers. When the adrenal vein is ligated, there can be a sudden drop in blood pressure. It is important to inform the anesthesiologist just before the adrenal vein is ligated to avoid any nasty surprises. Fluid repletion and pressors may be necessary to bring the pressure to normal.

With the emergence of minimally invasive surgery, access-related complications can occur. Bleeding from the abdominal wall can occur following trocar insertion. Care should be exercised to avoid visible superficial veins during trocar site insertion. Although bleeding usually stops from the tamponade effect of the trocar and pneumoperitoneum, it is imperative to inspect all trocar sites laparoscopically upon trocar withdrawal at end of surgery to ensure hemostasis. Cutaneous nerve injury is less likely to occur than in open surgery because of smaller incisions. Finally, visceral injury by the Veress needle can occur. Closed access technique using the Veress needle must be done with caution in patients with previous abdominal surgery as bowels may be adherent to the abdominal wall and can be injured. The open (Hasson) access technique can be a safer alternative in these cases.

Postoperative

Box 66-6 summarizes the postoperative complications that can occur. Disease-specific complications must be accounted for to ensure an uneventful postoperative course.

Patients with primary hyperaldosteronism require close monitoring of potassium levels because they can be either hypokalemic or hyperkalemic. Hyperkalemia, secondary to contralateral adrenal zona glomerulosa suppression, should be managed medically with

BOX 66-6 Postoperative Complications of Adrenal Surgery

PRIMARY ALDOSTERONISM

Hypokalemia: secondary to continued potassium loss immediately postoperative

Hyperkalemia: secondary to failure of contralateral adrenal to secrete aldosterone

CUSHING SYNDROME

Inadequate steroid replacement leading to hypocorticism

Fracture secondary to osteoporosis

Hyperglycemia

Poor wound healing

Increased risk of infections

PHEOCHROMOCYTOMA

Hypotension secondary to α -adrenergic blockade after tumor removal

GENERIC COMPLICATIONS

Hemorrhage

Pneumothorax

Pancreatitis

Pneumonia

Prolonged ileus

Intra-abdominal collections

Modified from Vaughn ED. Complications of adrenal surgery. In: Taneja SS, Smith RB, Ehrlich RM, editors. Complications of urologic surgery: prevention and management. 3rd ed. Philadelphia: Saunders; 2001. p. 368.

the typical hyperkalemia regimens. Hypokalemia can persist in the immediate period after adrenalectomy, and this should be corrected with potassium repletion. In patients who had only one adrenal gland to begin with, mineralocorticoid replacement with fludrocortisone is essential.

Patients with Cushing syndrome will require steroid replacement after surgery, until the contralateral gland recovers function. Measurements of plasma cortisol can be useful in determining when steroid replacement can be tapered. Furthermore, these patients have increased risk of fracture secondary to osteoporosis, hyperglycemia, and poor wound healing.

Patients with pheochromocytoma may have hypotension secondary to α -blockade. These patients need to be monitored closely until α -blockade wears off, often in the intensive care unit. If α -blockade was not used preoperatively, as is the protocol at the Cleveland Clinic, intensive care stay is unnecessary in most cases.

ABLATIVE THERAPY FOR ADRENAL TUMORS

Current indications for ablative therapy for adrenal tumors include patients with small tumors not keen on or suitable for surgery and palliation of painful metastases not amenable to resection. The three major thermal ablative techniques currently used are radiofrequency ablation (RFA), cryoablation, and microwave ablation. RFA utilizes frictional energy created by oscillating tissue ions to supply destructive heat to target tissue, with target tissue temperature ranging from 60° C to 100° C resulting in protein and enzymatic degradation and cell death. Microwave ablation creates an alternating electric field that causes oscillation of surrounding water dipoles resulting in tissue heating. Some authors have suggested that advantages of microwave ablation include the potential for larger ablation volumes, decreased procedural pain, and the potential to treat cystic

lesions (Simon et al, 2005). Cryoablation relies on rapid freezing and thawing to cause rupture of cell membranes resulting in cell death. The main advantage of this technique is the ability to follow iceball formation in real time with CT imaging.

It is generally recommended to perform a biopsy of the tumor either prior to or at the same session as ablative therapy because histologic results might influence follow-up management. Systemic catecholamine release resulting in hypertensive crisis and cardiac arrest has been reported during ablative treatment of adrenal metastases and pheochromocytomas (Chini et al, 2004; Mamlouk et al, 2009; Tsoumakidou et al, 2010). Since catecholamine release can be caused by thermal injury to the adrenal in the absence of pheochromocytoma, some authors advocate premedication with α -blockade prior to the ablation procedure. Welch and colleagues (2011) demonstrated a significant increase in systolic blood pressure, pulse pressure, and mean arterial pressures in patients undergoing adrenal cryoablation, even with prior α -blockade. Continuous blood pressure monitoring with an arterial line and general anesthesia with a rapid-acting vasodilatory drug on standby may be prudent.

Mendiratta-Lala and colleagues (2011) treated 13 hyperfunctioning small adrenal tumors with RFA. At a mean follow-up of about 21 months, all patients experienced resolution of clinical symptoms or syndrome and normalization of biochemical markers. The majority of current literature on ablative therapy is centered on treatment of metastases in the adrenal gland. The largest of these studies by Wolf and coworkers (2012) reported that 19 of 23 tumors treated showed no evidence of local progression and tumor enhancement at mean follow-up of 45.1 months after RFA or microwave ablation. Other studies also mirrored excellent short-term local progression-free and enhancement-free rates ranging from 83% to 100% after RFA, microwave ablation, or cryoablation (Mayo-Smith and Dupuy, 2004; Carrafiello et al, 2008; Wang et al, 2009; Welch et al, 2011). Nevertheless, evidence of long-term follow-up and outcomes are still lacking.

FUTURE OF ADRENAL SURGERY

Contemporary computer-based image acquisition systems are able to perform accurate 3D reconstruction of an organ or body region. Surgeons are now able to manipulate these 3D images such that the organ or body region could be viewed from almost all angles, allowing surgeons to acquire a mental picture of the regional anatomy they will be dealing with prior to surgery. Currently, virtual reality systems are being developed that will allow for the creation of a virtual environment where organs and structures can be represented in a fully 3D manner, in which surgeons can interact with the images as though they truly exist and perform tasks and surgical manipulations (Marescaux et al, 2005). In addition, the differentiation between the structure of the normal gland and pathologic lesions can be enhanced with high contrast and color, allowing for accurate localization of pathologic lesions and their relationship with the surrounding structures.

There are a few potential clinical applications for these virtual reality systems (Marescaux et al, 2005). First, by integrating with surgical simulators, residents and junior surgeons are able to gain surgical experience in a completely safe environment where errors could be made without detrimental consequences to the patient. Second, the integrated system can allow the surgeon to have an individualized “dry run” of a patient’s surgery prior to the actual

procedure, allowing for better planning as well as anticipation of possible dangers and identification of the optimal plane for dissection or resection. Finally, by integrating these virtual reality systems with advanced surgical robots in future, the digital data of the best simulated procedure performed by an expert could be recorded and transmitted to a distant remote location where a robot reproduces the surgery automatically on a patient.

The future of adrenal surgery remains exciting and fascinating.

KEY POINTS

- Adrenalectomy is indicated in functional adrenal masses or suspected adrenal malignancy, either primary adrenal cortical carcinoma or solitary metastasis from nonadrenal sources.
- Preoperative and postoperative medical management is essential for optimal surgical outcome for functional adrenal tumors.
- Laparoscopic adrenalectomy is the current standard of care for adrenal lesions with the exception of invasive adrenal cortical carcinoma or adrenal cortical carcinoma with caval thrombus.
- Open adrenal surgery is indicated for lesions contraindicated for or not amendable to minimally invasive techniques (e.g., large invasive carcinomas, great vessel involvement, severe cardiopulmonary diseases).
- It is imperative for all patients undergoing surgery for large adrenal masses to be counseled about the possibility of concurrent en bloc nephrectomy.
- It is recommended to perform a biopsy of the tumor either prior to or at the same session as ablative therapy.

Radiographic Anatomy

Female pelvic anatomy is one of the most complex areas of urosurgical anatomy. Pictures and descriptions alone are not enough to grasp fully the anatomy, as there is significant patient variation and many of the muscles and supportive structures are not clearly defined. There is also significant controversy and disagreement between the sources of terminology and the function of structures. This chapter aims to highlight the pertinent pelvic floor anatomy in a normal female. Many of the key structures will also be outlined in Chapter 68, and the current chapter will focus primarily on the important differences in females as compared to males. The radiographic and endoscopic anatomy will also be reviewed.

BONY PELVIS

The bony pelvis is the foundation that anchors the support structures of the female pelvis (Fig. 67-1). The true pelvis is made up of two hip bones or innominate bones (ilium, ischium, and pubis), as well as the sacrum and coccyx. The ilium is the fan-shaped portion of the hip bone that has an ala (wing) and body. The iliac crest is the rim of the ala between the anterior and posterior iliac spines. The ramus of the ischium forms part of the obturator foramen. **The ischial spine is a small posterior point between the ramus and the body of the ischium and is an important surgical landmark in pelvic reconstruction surgery.**

The pubic rami, ischial spines, and sacrum are some of the major anchoring points for the attachment of ligaments that support the bony pelvis. **The anterior and posterior compartments are divided by a line drawn between the two ischial spines.**

The pelvis is divided into the greater or false pelvis and the lesser or true pelvis by the plane at the level of the sacral promontory posteriorly and the terminal lines or pelvic brim. The pelvic brim also defines the pelvic inlet. The greater pelvis is a part of the lower abdominal cavity. The lesser or true pelvis is

the location of all the pelvic viscera and the area between the pelvic inlet and outlet.

Females have a wider diameter and a more oval inlet as compared to males. This aids in parturition but also contributes to weakness of the pelvic floor (Herschorn, 2004). The bones are also lighter and thinner compared to the male. Men have more clearly demarcated areas of muscular attachment, and women have smaller iliac fossa (MacLennan, 2012).

When the pelvis is visualized in the standing position, the anterior superior iliac spine and pubic symphysis lie parallel to each other (Barber, 2005). **The pelvic inlet faces anteriorly, which allows most of the pressure of the intra-abdominal and pelvic contents to be directed toward the bony pelvis rather than toward the muscles and the fascia (Fig. 67-2).** This is in contrast to the surgical anatomy, which is most commonly described in the lithotomy position.

FASCIA AND PERITONEUM

The fascia is divided into three strata:

1. Inner stratum
2. Intermediate stratum
3. Outer stratum

The rectal fascia is part of the inner stratum and covers the anterior and lateral rectal wall, vessels, and nerves forming part of Denonvilliers fascia. The intermediate stratum encases the uterus and supporting vessels and provides additional pelvic support. **Most of the support of the pelvic organs comes from the retroperitoneal connective tissue derived from the intermediate stratum.** This includes the pubovesical and pubocervical fascia that surround the vagina. The fascia attached to the uterus is referred to as the parametrium and that surrounding the vagina is the paracolpium (Wei and DeLancey, 2004) (Fig. 67-3).

The transversalis fascia is part of the outer stratum and is continuous with the endopelvic and lateral pelvic fascia. Both the

Figure 67-1. The bones and ligaments of the pelvis. l., ligament. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 67-2. Pelvis in standing position. The axis of the pelvic cavity is horizontal because of the lumbar lordosis. (From Zacharin RF. *Pelvic floor anatomy and the surgery of pulsion enterocele*. New York: Springer-Verlag; 1985.)

transversalis and endopelvic fascia play important roles at the exit points of the pelvic organs. The endopelvic fascia extends from the uterine artery down to where the vagina and levator ani fuse. The iliac fascia is also part of the outer stratum and covers the iliacus and psoas muscles. It attaches to the iliac crest and runs down to the tendinous arch (white line) and is continuous with the posterior portion of the inguinal ligament. It is also continuous with the pectineal fascia and obturator fascia. The obturator fascia covers the obturator internus and piriformis muscles.

The thickened band of the pelvic fascia that runs from the ischial spine to the pubic bone is called the tendinous arch or the arcus tendineus. It is also known as the **arcus tendineus fasciae pelvis (ATFP)** where many of the important fascial layers attach. It originates from the pubic bone laterally and is connected to the pubovesical ligament medially and the tendinous arch of the levator ani (Fritsch et al, 2012). This is the remnant of the degenerate tendon of iliococcygeus. This should not be confused with an adjacent structure that bears a similar name. The **arcus tendineus levator ani (ATLA)** is where the muscles of the levator ani attach. The ATLA is the aponeurotic portion of the obturator fascia covering the obturator internus muscle.

The inferior pelvic fascia is continuous with the obturator fascia and fascia of the pudendal canal. It covers the surface of the levator ani. The superior pelvic fascia arises from the outer stratum and the obturator fascia. It runs from the pubic symphysis laterally to the ischial spine. The fascia is thinner over the muscles and organs, allowing more mobility.

There are six main potential spaces that exist among the pelvic organs. In the midline, there are the vesicovaginal and the rectovaginal spaces. The vesicovaginal space is contained by the adventitia of the bladder anteriorly and vagina posteriorly. The space ends where the vagina fuses with the distal urethra and at the vesicocervical ligament (fusion of the bladder with the vagina and cervix). The prevesical space is between the fascia covering the bladder and the endopelvic fascia behind the pubis. This space extends laterally to

Female: superior view (peritoneum and loose areolar tissue removed)

Figure 67-3. Fascia of the pelvis and potential spaces. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

the obliterated umbilical artery. The **retrorectal space** is between the rectal fascia and transversalis fascia over the sacrum. Laterally there are the **paravesical** and **pararectal spaces**, which sit adjacent to their respective organs.

The **pouch of Douglas** or **rectouterine pouch** is formed by a fold of peritoneum (rectovaginal fold) that extends between the

uterus and rectum. It is bound by the uterus, posterior vaginal fornix, rectum, and uterosacral ligaments. The **vesicouterine pouch** is demarcated by a fold of peritoneum (utero-vesical fold) reflected onto the bladder from the uterus located just at the junction of the uterine body and cervix. The peritoneum also forms the **uterosacral fold** between the pararectal and paravesical fossae.

LIGAMENTS

There are several pelvic ligaments of importance to urosurgical anatomy: the **sacrospinous**, **sacrotuberous**, and **sacroiliac** ligaments. The sacrospinous ligament attaches from the ischial spine to the lateral border of the sacrum and crosses in front of the sacrotuberous ligament, fusing with it medially. The **coccygeus muscle covers the sacrospinous ligament**. Above this lies the **sciatic nerve and plexus**, which is an important structure to avoid during vault suspensions. The sacrotuberous ligament attaches from the ilium and ischium to the sacrum. It runs from the posterior iliac spine along the sacral border and attaches to the ischial tuberosity. The greater and lesser sciatic foramina run above and below this ligament (Rosenblum et al, 2005).

Posteriorly there are also short and long dorsal sacroiliac ligaments that connect the sacrum to the ilium. The sacrospinous ligament lies in continuity with the sacrococcygeal ligament. The iliolumbar ligament connects the fifth lumbar vertebrae to the ilium (Fig. 67-4).

In addition, condensations of the transversalis fascia form ligamentous structures that help to support the pelvic organs. These include the pubovesical ligaments, vesicopelvic ligaments, pubocervical fascia, and cardinal and uterosacral ligaments.

The **pubovesical ligaments (pubourethral ligament)** are homologous to the **puboprostatic ligaments** in males and run from the pubic bone to the bladder neck. They are important structures in retropubic suspension; they hold the bladder neck in place when it contracts, and they provide a hammocklike support to the mid-urethra. The **vesicopelvic ligament or fascia is formed from fusion of the perivesical and endopelvic fascia**. It extends from the base of the bladder and anterior vaginal wall and attaches to the tendinous arch. It is continuous with the periurethral fascia and the uterine cervix and cardinal ligaments. Defects in this fascia or ligament can result in lateral cystocele defects (MacLennan, 2012).

The **broad ligament** contains the fallopian tube and ovary and lies on the posterolateral surface of the uterus attaching it to the pelvic wall. It is formed by peritoneum extending from the anterior and posterior surfaces of the uterus. Within the mesometrium of

the broad ligament are the uterine artery, veins, and nerves. The broad ligament also contains the mesosalpinx, which has a vascular network between the uterine tube and ovary. The **round ligament (present within the broad ligament)** exits at the internal inguinal ring and crosses over the external iliac artery and terminates in the mons pubis of the labium majus. It attaches the lateral walls of the uterine body to the pelvic sidewalls. It contains the ovarian ligaments and is homologous to the gubernaculum of the male. Behind the broad ligament lies the infundibulopelvic ligament (suspensory ligament of the ovary), which runs from the ovary to the lateral surface of the uterus beneath the entrance of the fallopian tube. It contains the ovarian vessels (Fig. 67-5).

Within the parametrium are the important **cardinal and uterosacral ligaments**. There are blood vessels, nerves, smooth muscle, adipose, and connective tissue that lie near these ligaments. Nerves from the pelvic plexus travel through the cardinal and uterosacral ligaments with the vessels, and damage to these during a hysterectomy can result in bladder dysfunction. The **uterosacral (sacrouterine) ligaments** originate from the greater sciatic foramen and insert into the lateral aspect of the fascia that encircles the cervix, isthmus of the uterus, and vaginal wall. They contain fibrous tissue and smooth muscle. They are often used as anchoring structures in apical suspensions. The **ureter lies lateral to the anterior portion of the uterosacral ligament** (closest at the area of the cervix). There is potential for sacral nerve entrapment (S1 and S2 to S4 nerve trunks) during a suspension as the nerve crosses over these areas dorsally (Ramanah et al, 2012).

The **cardinal ligaments** fuse posteriorly with the uterosacral ligaments and stabilize the uterus, cervix, and upper vagina (Fig. 67-6). They originate from S2 to S4 and insert into the posterolateral aspect of the pericervical fascia and lateral vaginal wall. They run under the rectovaginal peritoneum and contain the major blood vessels from the internal iliac artery. The paracolpium suspends the superior aspect of the vagina to the pelvic wall.

The **ureter is vulnerable to injury as it passes near the ligaments that support the uterus and ovary (Fig. 67-7)**. It crosses the infundibulopelvic ligament under the ovarian artery and is just medial to the uterine artery. It also passes near the cardinal ligament and lies in close proximity to the cervix.

Figure 67-4. Ligaments of the pelvis. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 67-5. The broad ligament of the uterus and its contents. (From Standring S. *Gray's anatomy: the anatomical basis of clinical practice*. 40th ed. London: Churchill Livingstone; 2008.)

MUSCLES OF THE PELVIC FLOOR

Pelvic Sidewalls

The walls of the pelvis are formed by the obturator internus, iliacus, psoas major and minor, levator ani system, and the coccygeus.

The obturator internus covers most of the lateral pelvic sidewall. It passes through the lesser sciatic foramen and attaches to the greater trochanter of the femur. The piriformis muscle covers and pads the pelvic wall posterolaterally. It passes through the greater sciatic foramen to attach to the greater trochanter of the femur and is associated with the sacral plexus medially.

Pelvic Floor

The pelvic floor is composed of the pelvic diaphragm, which extends from the pubis anteriorly to the coccyx posteriorly. **It is composed of the levator ani muscles and plays an important role in support of the urogenital viscera as well as their function.** The levator ani complex consists of the **pubococcygeus, puborectalis, and iliococcygeus**. The name of each of its components is derived from their attachments. The **pubococcygeus originates at the posterior portion of the pubis and arcus tendineus** and attaches to the visceral organs and anococcygeal raphe. It can be subdivided into smaller muscles that are not well delineated and can be named after the structures they surround. These include the pubourethralis, pubovaginalis, and puboanalis (together referred to as the pubovisceralis). The pubococcygeus plays an active role in visceral control. It forms a sling around the urethra and vagina and is known as the pubovaginal muscles. The puborectalis is part of the pubococcygeus and originates on the pubic bone and forms a muscular sling around the vagina, rectum, and perineal body. **The iliococcygeus originates at the obturator fascia and ischial spine.** The muscles meet in the midline to form the anococcygeal ligament or raphe. The opening of the levator ani muscle group is referred to as the levator hiatus and allows passage of the urethra, vagina, and rectum. The fascial attachments provide additional support to the viscera. **The levator plate is created by the fusion of the levator ani muscles in the midline and serves as a shelf on which the viscera rest.** Weakening of the levator ani may cause the plate to sag and open the hiatus, predisposing to pelvic organ prolapse (Herschorn, 2004).

The ischiococcygeus is sometimes referred to as the coccygeus. This muscle extends from the ischial spine to the coccyx and sacrum and contributes to the posterior part of the pelvic diaphragm. It sits anterior to the sacrospinous ligament. The coccygeus and iliococ-

cygeus are thought to be innervated by divisions of the pudendal nerve, inferior rectal nerve, and perineal nerve, but more recent studies describe its innervation solely from the levator ani nerve originating from S3, S4, and S5, which travels medial to the ischial spine and ATLA (Barber, 2005).

There is a constant resting tone to the pelvic floor muscles that help support the pelvic viscera, resist increases in intra-abdominal pressure, and play an important role in passive control of urinary and fecal continence. When there is loss of this tone resulting from muscle or nerve injury, the urogenital hiatus becomes more lax and there is a lessening of the horizontal orientation of the levator plate (Barber, 2005) (Fig. 67-8).

VASCULATURE OF THE PELVIS

The vascular anatomy will be reviewed in detail in Chapter 33, but there are some pertinent differences in the female pelvic vascular anatomy that need to be noted.

The internal iliac artery (hypogastric artery) branches into a posterior and anterior division. **The uterine artery arises from the anterior trunk and enters the broad ligament and cardinal ligament.** It branches into an ascending branch that anastomoses with the ovarian and fallopian tube arteries as well as with a descending limb that supplies the cervix and vagina. **The uterine artery passes in front of the ureter, making the ureter vulnerable to iatrogenic injury during division of the uterine pedicle.**

The venous drainage of the pelvis parallels the arteries but contains an intricate network of plexuses (uterine, vaginal, retropubic, vesical, rectal). The internal iliac vein is the main venous drainage from the pelvis running posteromedial to the artery. The internal pudendal vein drains the corresponding structures that the artery supplies and drains directly into the internal iliac vein. The obturator vein lies posterior to the artery and ureter and drains into the internal iliac vein. The superior and inferior gluteal veins, lateral sacral veins, and middle rectal and rectal venous plexuses also drain directly into the internal iliac vein. The clitoral veins drain into the retropubic plexus, which is much smaller relative to the Santorini plexus in the male. The retropubic plexus drains through the vesical plexus, which lies over the anterior portion of the bladder (in continuity with the uterine plexus) and subsequently drains into the internal iliac vein. The retropubic plexus also receives blood from the external genitalia and rectum. The uterine and vaginal plexuses communicate with each other and drain into the internal iliac vein.

The external iliac vein is a continuation of the femoral vein and drains the inferior epigastric vein, deep circumflex iliac, and pubic veins (Fig. 67-9).

LYMPHATIC DRAINAGE

The internal iliac nodes lie near the origin of the uterine, pudendal, and middle hemorrhoidal arteries. They drain the bladder, uterus, rectum, and perineum. They then communicate and drain into the middle chain of the common iliac nodes.

The external iliac nodes are divided into three chains: external, middle, and internal. The clitoris and abdominal wall drain into the superficial and deep inguinal nodes that feed the external chain. The bladder, uterus, and vagina drain into the middle chain that lies over the external iliac artery. The internal chain drains the lower abdominal wall, clitoris, superficial and deep inguinal nodes, bladder neck, and urethra. More details of lymphatic drainage will be highlighted throughout the remainder of the chapter.

INNERVATION

The innervation is also reviewed in Chapter 68. The sacral plexus is formed from the ventral rami of L4 to L5 and S1 to S3 and lies on the piriformis muscle deep to the endopelvic fascia and posterior to the internal iliac vessels. **It exits the pelvis through the greater**

Figure 67-6. Ligament and support of the vagina and uterus. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

sciatic foramen immediately posterior to the sacrospinous ligament and can be injured during a sacrospinous culdosuspension. It supplies motor and sensory innervation to the posterior thigh and lower leg. Exaggerated lithotomy position may stretch this nerve or place pressure on its peroneal branch at the fibular head to produce foot drop.

Pelvic and perineal branches of the sacral plexus include the posterior femoral cutaneous nerve (S2, S3) that passes through the

greater sciatic foramen and has a sensory branch to the perineum. It also includes the pelvic somatic efferent nerves from the ventral rami of S2, S3, and S4. They travel on the pelvic surface of the levator ani, innervating these muscles as well as the striated urethral sphincter.

The pudendal nerve arises from S2 to S4 just above the sacrotuberous ligament and ischiococcygeus. It passes through the greater sciatic foramen and crosses the piriformis and

Figure 67-7. Close relationship of ureter to the uterine structures. a., artery; l., ligament. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

the bladder base, which then yields the vesical plexus and utero-vaginal plexus that sends fibers through the broad ligament. The parasympathetic fibers usually lie deeper to the sympathetic fibers within the intermediate stratum.

PERINEUM

The borders of the perineum are the pubic symphysis anteriorly, pubic rami and ischial rami anterolaterally, ischial tuberosities laterally, sacrotuberous ligaments posterolaterally, and sacrum and coccyx. It is divided into the anal triangle posteriorly and urogenital triangle anteriorly by a line connecting the ischial tuberosities. The perineal membrane (previously called the urogenital diaphragm) is a sheet of fascia that lies between the two sides of the pubic arch. The urethra and vagina pass through the urogenital hiatus of the perineal membrane to exit at the vestibule.

The perineal membrane divides the urogenital hiatus into a superficial and deep perineal space. It attaches laterally to the ischiopubic rami, and its apex is attached to the arcuate ligament of the pubis. The posterior border is fused with the perineal body. The deep space contains the external urethral sphincter, urethrovaginalis, compressor urethrae, and deep transverse perineal muscles. The inferior fascia of the urogenital diaphragm is what lays the groundwork for the deep space. The superficial space is made up of the superficial perineal muscles, clitoris, vestibular bulbs (bulbospongiosus), and Bartholin glands. Bartholin glands are homologous to Cowper glands but lie more superficially. Colles fascia or the membranous layer of the superficial fascia covers the superficial perineal space. It attaches laterally to the pubic rami and the ischial tuberosities. Posteriorly it meets the perineal membrane and anteriorly covers the clitoris similar to the dartos fascia in the male. The deep perineal fascia lies over the superficial muscles of the perineum and fuses with the suspensory ligament of the clitoris and fascia of the rectus sheath and external oblique muscles.

The perineal body is at the central point of the perineum and consists of muscle and collagenous and elastic fibers. It is the convergence of the bulbospongiosus, external anal sphincter, and superficial and deep transverse perineal muscles. It is posterior to the vestibule of the vagina and anterior to the anal canal and attaches to the posterior border of the perineal membrane. Damage to the perineal body during parturition can result in damage to the fibers of the external anal sphincter. An episiotomy is angled laterally to avoid damage to these fibers.

The bulbospongiosus splits to surround the introitus and attaches anteriorly to the clitoris. It attaches to the perineal body and covers the vestibular bulbs. They contract to constrict the vaginal orifice and express vestibular gland secretions. The ischio-cavernosus also covers one crus of the clitoris and promotes its erection. The superficial transverse perineal muscles overlie the posterior portion of the vagina.

Figure 67-8. Muscles of the true pelvis (three-quarter view).

ischiococcygeus as well as the sacrospinous ligament close to the area where it attaches to the ischial spine. This also makes it vulnerable to injury during a sacrospinous ligament culdosuspension. It then runs medially to the internal pudendal vessels as they travel through the lesser sciatic foramen into the Alcock canal. The pudendal nerve has three branches: (1) inferior rectal nerve, (2) perineal nerve, and (3) dorsal nerve of the clitoris. The perineal branch divides into the posterior labial branch to supply the labium majus, superficial and deep transverse perineal muscles, external anal sphincter, and levator ani. The pudendal branches carry efferent impulses to muscles of the pelvic floor and proprioceptive afferent signals and sensation from the urethra.

The superior hypogastric plexus arises from the aortic plexus below the aortic bifurcation at L5. It bifurcates into the left and right hypogastric nerves that unite with the pelvic splanchnic nerves. The right and left pelvic (hypogastric) plexuses lie near

Figure 67-9. Arterial supply of the pelvis. (From Standring S. *Gray's anatomy: the anatomical basis of clinical practice*. 40th ed. London: Churchill Livingstone; 2008.)

The perineum is supplied by the internal pudendal artery, which travels through the perineal membrane and branches into the posterior labial branches, the artery of the bulb to the erectile tissue of vestibular bulbs, and the arterial supply to the clitoris and corpus cavernosum (Fig. 67-10).

ANAL PERINEUM

The rectum is covered in pararectal fascia that connects the anorectal junction to the sacrum. Anteriorly there is rectovesical fascia and posterolaterally there are lateral ligaments of the rectum that run with the middle rectal vessels. The anococcygeal ligament also provides anal canal support and runs between the middle of the external anal sphincter and the coccyx.

The ischioanal fossa contains fat and Colles fascia and is bound by the external anal sphincter, ischial tuberosity, urogenital diaphragm, and gluteus maximus. The internal pudendal vessels run on the lateral wall of the fossa inside Alcock canal. The internal rectal venous plexus lies between the rectum and puborectalis and levator ani muscles. The external plexus lies deep to the sphincters. They both drain into the middle rectal vein. The superior rectal vein drains into the inferior mesenteric vein and the inferior rectal vein drains into pudendal vein.

The external anal sphincter is composed of striated muscle and has three parts. From distal to proximal, they include the subcutaneous external anal sphincter, the superficial external sphincter, and the deep external sphincter. The deep external anal sphincter is adjacent to the deep transverse perineal muscles and the levator ani. The external anal sphincter is innervated by

the inferior rectal nerve and by branches of the pudendal nerve. The internal anal sphincter is a circular nonstriated muscle lying outside the internal rectal venous plexus. It receives autonomic innervations from branches of the iliohypogastric plexus. Fecal continence is complex and depends on the integrated function of the internal and external anal sphincters, the puborectalis muscle, intact neurosensory pathways, rectal compliance, anorectal sensation, and anal sphincter resting tone.

EXTERNAL GENITALIA

The **mons pubis** is the hair-bearing area of skin overlying the pubic symphysis. The hymen is composed of folds of mucous membranes that lie at the entrance of the vagina. The **labia majora** frame the vagina laterally and fuse anteriorly at the hood of the clitoris and are the homolog of the scrotum. The mons pubis is continuous with the labia. The **labia minora** are fat free and hairless and immediately surround the vestibule of the vagina. They contain erectile tissue, and blood vessels are connected by the frenulum or fourchette.

The clitoris is bounded by the labia minora, by the prepuce dorsally, and ventrally by the frenulum. It is composed of a root, body, and glans. There are two corpora cavernosa that split as crura proximally to attach to the inferior ischiopubic rami and are surrounded by the ischiocavernosus. They fuse distally and terminate as the glans, which is composed of spongy erectile tissue and is connected to the bulbs by bands of erectile tissue. The erectile bodies are composed of the bulbar commissure ventrally and the bulbs of the vestibule, which are covered by bulbospongiosus

Figure 67-10. Female superficial perineal pouch. Left, the muscles have been removed to show the vestibular bulb and Bartholin gland. (From Williams PL, Warwick R. *Gray's anatomy*. 35th British ed. Philadelphia: Saunders; 1973.)

Figure 67-11. Female vulva and external genitalia. (From Standring S: *Gray's anatomy: the anatomical basis of clinical practice*. 40th ed. London: Churchill Livingstone; 2008.)

muscle. Bartholin glands are at the end of each bulb and travel 2 cm to empty through the groove between the hymen and labia minora. These glands can become obstructed and present as Bartholin gland cysts.

The vulva has lymphatic drainage into the superficial inguinal glands. These then drain to the deep inguinal nodes that travel to the pelvic nodes. The clitoris and labia minora drain to the deep inguinal nodes and may pass to the internal iliac nodes (from the clitoris).

The innervation to the anterior labium majus comes from branches of the ilioinguinal nerve, which arises from T12. Branches from the perineal nerve innervate the posterior two thirds. Laterally there is also innervation from the perineal branch of the cutaneous nerve of the thigh. Parasympathetic stimulation results in increased vaginal secretion, erection of the clitoris, and engorgement of the erectile tissues (Figs. 67-11 and 67-12).

FEMALE PELVIC ORGANS

The uterus is composed of the uterine body and the cervix and is normally anteverted and anteflexed. The cervix terminates as the

os into the vagina. It is surrounded by the vaginal wall that is shallow anteriorly (ventral fornix) and deeper posteriorly (dorsal fornix) along with lateral fornices. The cervix is usually 2.5 cm long (Standring, 2008). The cervix is adjacent to the bladder and is separated only by the parametrium. **The body of the uterus is composed of three layers.** The outermost layer is the **perimetrium**, which is the peritoneum and thin connective tissue (parametrium). The **myometrium** is broken down into three additional layers: outer longitudinal layer continuous with the ovarian and round ligament, middle circular layer, and inner longitudinal layer. The blood vessels and nerves are located in this layer. The innermost layer of the uterus is the **endometrium** or mucosal layer.

The uterine artery is a branch off the anterior branch of the internal iliac artery. It crosses the ureter close to the cervix and also provides a small branch to the ureter. It passes through the broad ligament and feeds the fallopian tube, and it then runs laterally and joins the ovarian artery. There are branches to the cervix and the cervix terminates as the azygos arteries of the vagina. The uterus drains into a uterine plexus that runs in the broad ligament and joins the vaginal and ovarian plexuses to drain eventually into the internal iliac vein. Innervation is from the uterovaginal plexus, which originates from the inferior hypogastric plexus.

Figure 67-12. Arteries and nerves of the female perineum. (From Doherty MG. Clinical anatomy of the pelvis. In: Copeland LJ, editor. Textbook of gynecology. Philadelphia: Saunders; 1993. p. 51.)

Figure 67-13. Female internal genitalia, from behind. The ureter passes beneath the uterine artery. a., artery; l., ligament. (From MacLennan GT. Hinman's atlas of urosurgical anatomy. 2nd ed. Philadelphia: Saunders; 2012.)

The lymphatic drainage of the uterus is complex. The cervix drains into the external and internal iliac nodes as well as the sacral nodes. The upper part of the uterus and fallopian tubes follow the ovary drainage into the lateral aortic and preaortic nodes. Around the area of the round ligament, there is drainage into the superficial

inguinal nodes. The uterine body drains into the external iliac nodes. The fundus drains into the para-aortic and lateral aortic nodes (Fig. 67-13).

The uterine or fallopian tubes are 10 to 12 cm in length and are draped in the broad ligaments. They open posteromedially

and are divided into four parts: uterine interstitial segment, isthmus, ampulla, and infundibulum. They terminate with fimbriae. They enter the uterus bilaterally at the uterine cornua. There is arterial supply from both the ovarian and uterine arteries. The lateral two thirds drain into the ovarian veins and the medial portion drains into the uterine plexus. Lymphatic drainage is to the para-aortic nodes (ovarian vessels), internal iliac chain (uterine vessels), and inguinal nodes (round ligament). Innervation is by autonomic fibers from the ovarian and uterine plexuses.

The ovaries are supported by the mesovarium and are in the ovarian fossa in the posterior peritoneum, which is bordered by the obliterated umbilical artery, ureter, and internal iliac artery. The ovary is attached to the posterior aspect of the broad ligament and is suspended by the infundibulopelvic ligament, which contains the ovarian vessels. It is also attached to the uterus by the ovarian ligament. The ovarian artery arises directly from the aorta and passes in the infundibulopelvic ligament into the hilum of the ovary. It then passes through the broad ligament supplying the fallopian tube and joins the uterine artery. The venous drainage of the ovary is to a pampiniform plexus that merges into the ovarian vein. Similar to the testicle, the drainage of the right vein drains directly into the vena cava below the renal vein and the left drains into the left renal vein. Innervation is from the ovarian plexus and inferior mesenteric plexus and it follows the path of the ovarian artery. The lymphatic drainage is also similar to the testicle and drains into the lateral aortic and preaortic nodes near the kidneys.

The vagina appears H shaped when cross sectioned and contains rugae or folds. There are columns that run on the anterior and posterior walls terminating at the urethrovaginal ridge or carina. The vagina is composed of a mucous membrane and lamina propria that are fixed to the muscular layer. The muscle has an outer longitudinal and an inner circular layer that are attached to the rectovesical fascia on either side. The muscle is lined by nonkeratinized stratified squamous epithelium. The vaginal wall is attached to the cervix higher on the posterior wall compared to the anterior wall. Therefore the anterior wall is about 7.5 cm on average, and the posterior wall is 9 cm. There are remnants of the ducts of Gartner that can protrude through the lateral fornices of the vagina, and when obstructed they can lead to Gartner cysts.

The vagina is attached anteriorly by the levator ani at the arcus tendineus and posteriorly to the rectovaginal septum. The apex is covered by the peritoneum from the rectouterine pouch. The base of the bladder rests on the vaginal wall and is tethered together by smooth muscle fibers that need to be opened to access the vesicovaginal space. The ureters pass close to the lateral fornices of the vagina and are anterior to the vagina as they enter the bladder. Access to the retropubic space can be obtained by incising the anterior vaginal wall on either side of the urethra.

The vessels and nerves lie on the anterolateral surface of the vagina deep to the ATFP. The uterine arteries supply the superior part of the vagina. The middle and inferior portion of the vagina are supplied by the vaginal arteries (branches of the uterine and middle rectal artery). The inferior portion is supplied by the internal pudendal artery. The vaginal venous plexus joins the uterine plexus to form the uterovaginal venous plexus. The superior portion of the vagina includes lymphatic drainage into the internal and external iliac lymph nodes. The middle portion drains into the internal iliac lymph nodes, and the inferior portion into the sacral and common iliac nodes as well as the superficial inguinal nodes.

The vagina has autonomic innervation from the uterovaginal plexus (sympathetic, parasympathetic, and visceral afferent fibers), which travels at the base of the broad ligament. The lower one fourth of the vagina also has somatic innervation from the pudendal nerve and is sensitive to touch and to temperature changes.

PELVIC ORGAN SUPPORT

The pubovesical ligaments help support the urethra and bladder neck but may also play a role in relaxation of the bladder neck

Figure 67-14. Vaginal and visceral supportive structures as defined by DeLancey. The fibers of level I support are oriented vertically and suspend the uterus and upper vagina. Level II support is more horizontal in its orientation and is attached to the mid vagina. Distally, level III support fuses directly into the support structures. (From DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717–28.)

during micturition (Herschorn, 2004). Whether or not there is any true fascia at the anterior vaginal wall is controversial. However, the anterior vagina does provide support to the urethra through its lateral attachment to the pubococcygeus and ATFP. The pubocervical fascia that extends from the pubic symphysis to the cervix (another disputable structure) may provide additional support to the bladder base (Herschorn, 2004).

The parametrium and paracolpium provide support to the vagina and uterus. The cardinal ligaments and uterosacral ligaments also provide additional support to the uterus, cervix, and upper vagina. This is level I support as originally described by DeLancey (Wei and DeLancey, 2004), which supports the uterus and the vaginal apex. The broad ligament and round ligament do not play a significant role in pelvic organ support (Barber, 2005). Weakness of the lateral attachments of the cardinal ligaments or vesicopelvic ligaments leads to lateral cystocele defects. The posterior vaginal wall is supported by the paracolpium that attaches to the rectovaginal fascia (Herschorn, 2004). This sheet of fascia at its medial aspect of the vagina is sometimes referred to as the rectal pillars (Ashton-Miller and DeLancey, 2007). Level II support is from the paravaginal attachments to the ATFP (Barber, 2005) and to the arcus tendineus rectovaginalis. Level II support is for the anterior vaginal wall, and loss of this support can lead to anterior wall prolapse. The distal vagina is directly attached to the surrounding structures fusing with the urethra and perineal membrane (Level III support). Laterally it attaches to the levator ani muscles and fuses with the perineal body. Level III support relates to the urethra, and disruption of this support results in urethral hypermobility (Fig. 67-14).

URETHRA

The anatomic length of the female urethra is about 4 cm from the internal to the external urethral meatus. The urethra lies just anterior to the vagina below the pubic bone.

The urethra is composed of three anatomic layers: (1) epithelium, (2) submucosa, and (3) mucosa. The urethra is made up of the transitional epithelium with multiple infoldings that allow distensibility and coaptation on closure. This transitions to the pseudostratified and squamous epithelium at the most distal portion. It is

surrounded by a spongy tissue of vascular networks that make up the submucosa, which is similar to the corpus spongiosum in a male. Surrounding this is a thin periurethral fascia. **The mucosa and submucosa are the primary contributors to urethral closure pressure and are estrogen dependent.** There is a proximal and distal venous plexus that runs under the epithelium that may also play a role in urethral closure. Aneurysms may form in these plexuses.

There are many periurethral glands around the urethra that, when obstructed, can give rise to diverticula. The most prominent are Skene glands, which open distally just inside the meatus.

External to the urethra are two layers of smooth muscle, an inner longitudinal and an outer circular, which are continuous with the muscle layers of the bladder and constitute the involuntary urethral sphincter. These muscle layers are surrounded by elastic tissue and collagen. The longitudinal fibers shorten the urethra and increase the diameter for voiding (MacLennan, 2012). **At the distal two thirds of the urethra, the voluntary sphincter is present, which is composed of striated muscle.** At the most proximal portion (midurethra) it forms a horseshoe around the urethra. This is where the urethral closing pressure is highest. **There are muscle fibers on the lateral sides of the urethra that are continuous with the anterior and lateral walls of the vagina (urethral compressor).** When they contract, it results in closure of the urethra against the anterior vaginal wall. There are additional fibers that surround both the urethra and the vagina that compose the urethrovaginal sphincter. When these fibers contract, they tighten the urogenital hiatus. The pubococcygeus runs alongside the urethra on either side and has some function to increase resistance in the urethra. Innervation comes from both pudendal and somatic nerves that travel on the lateral vaginal wall. The somatic nerves innervate the striated urethral sphincter through the ventral root of S3 and some from S2.

Blood supply to the urethra comes from the inferior vesical, vaginal, and internal pudendal arteries. The venous drainage is carried through the inferior, middle, and superior vesical veins as well as the clitoral plexus into the internal pudendal veins. The distal one third of the urethra (anterior urethra) drains into the superficial and deep inguinal lymph nodes. The proximal two thirds (posterior urethra) drains into the iliac and obturator lymph nodes (Fig. 67-15).

RADIOGRAPHIC ANATOMY

There are many different modality images that are used to visualize the female pelvis and its contents.

KEY POINTS: SURGICAL ANATOMY OF THE FEMALE PELVIS

- The bony pelvis should be visualized in the supine position. Here the pelvis is oriented in such a fashion that allows most of the pressure of the intra-abdominal and pelvic contents to be directed toward the bony pelvis.
- The ATPF and ATLA are two distinct structures that should not be confused with each other.
- The ureter is vulnerable to injury during a hysterectomy because it comes into close proximity to the cervix and to the blood supply of the uterus and ovaries.
- The levator ani muscles (pubococcygeus, puborectalis, and iliococcygeus) and coccygeus make up the pelvic floor muscles and have a constant resting tone that helps support the pelvic viscera and resist increases in intra-abdominal pressure. They also play a role in fecal and urinary continence.
- Both the sacral plexus and the pudendal nerve are at risk of injury during a sacrospinous culdosuspension.

Fluoroscopy

Fluoroscopy is often used to obtain real-time imaging, especially to capture dynamic pictures of the bladder and urethra during voiding. It uses a low dose of radiograph beams that pass to an image intensifier (Raman and Boyadzhyan, 2008b) and to a high-resolution monitor. A cystogram is performed by taking static images of the bladder in different views after contrast is instilled. It usually includes a postdrainage picture of the bladder. It is used to diagnose bladder perforations, intravesical filling defects, and diverticula. Low-pressure fistulae to the bladder can also be visualized.

A voiding cystourethrogram (VCUG) takes dynamic pictures during voiding after contrast is instilled into the bladder and the Foley is subsequently removed. This test is often used concurrently with urodynamics (videourodynamics) to correlate dynamic with radiographic findings. This is especially helpful to evaluate the urethra and bladder outlet anatomy during voiding. Vesicoureteral reflux and vesical fistulae can also be diagnosed on VCUG. Urethral obstruction and diverticula can also be seen. High-grade cystoceles are easily seen on VCUG as well.

Figure 67-15. Urethra and its supportive structures that help to maintain continence. m., muscle. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 67-16. Axial T2 half-Fourier acquisition single-shot turbo spin-echo magnetic resonance imaging of normal female pelvic anatomy.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is one of the most helpful tools to visualize pelvic floor structures without the use of radiation. It provides well-delineated imaging of tissues such as muscle, fat, fluid, and blood (Raman and Boyadzhyan, 2008a). In pelvic floor imaging, the half-Fourier acquisition single-shot turbo spin-echo (HASTE) or single-shot fast spin-echo (SSFSE) T2-weighted sequences are often used. These provide quick, noninvasive multiplanar surveys of the abdomen and pelvis as well as dynamic studies to visualize the pelvic floor during relaxed and strained states (Raman and Boyadzhyan, 2008a). The obturator internus and levator ani muscles are well visualized by MRI (Fig. 67-16). T1-weighted imaging with gadolinium contrast is useful for visualization of the kidneys and ureters. T2-weighted imaging is useful to differentiate masses, cysts, and tissue parenchyma.

Pelvic MRI is useful in differentiating cystic lesions in the vagina and urethra. Some benign vaginal cysts include müllerian cysts, epidermal inclusion cysts, Gartner duct cysts, Bartholin gland cysts, and Skene gland cysts. MRI is the best imaging technique to visualize and localize urethral diverticula and to differentiate them from other benign vaginal cysts (Walker et al, 2011).

The uterus is imaged on T2-weighted MRI, which delineates its three zones: endometrium, junctional zone, and myometrium (Fig. 67-17). The endometrium and uterine cavity have high signal, whereas the junctional zone has low signal. The outer myometrium has medium to high signal. It is a great imaging modality to assess for leiomyomas and adenomyosis as well as to determine the vascular supply and staging endometrial and cervical cancer (Raman and Boyadzhyan, 2008b). Endometrial implants can also be diagnosed on MRI as well. Although adnexal imaging is performed primarily via ultrasonography, MRI can help provide better definition in certain cases such as differentiating malignancy from benign adnexal masses.

MRI can be used for the diagnosis and staging of pelvic organ prolapse. Midsagittal and parasagittal resting and straining supine views are obtained for evaluating the different compartments, pelvic floor muscles, and pelvic organs (Fig. 67-18). These images are often looped as a cine stack and are measured to fixed anatomic landmarks to determine the grade of pelvic organ prolapse and pelvic floor relaxation (Comiter, 2005). Measurements obtained include the “H-line,” or levator hiatus width, measured from the pubis to the posterior anal canal. The “M-line,” or muscular pelvic floor relaxation, measures the distance from the levator plate to the pubococcygeal line. The “O” classification is then assigned to the degree of prolapse beyond the “H-line” as 0, 1, 2, or 3 (no, mild, moderate, or severe) (Comiter et al, 1999).

Figure 67-17. Normal anatomy of the pelvic structures on T2-weighted magnetic resonance image showing the zonal anatomy of the uterus. (From Standing S. Gray's anatomy: the anatomical basis of clinical practice. 40th ed. London: Churchill Livingstone; 2008.)

Figure 67-18. Dynamic half-Fourier acquisition single-shot turbo spin-echo sequence T2-weighted magnetic resonance image in a patient with minor prolapse. H-line measures levator hiatus, M-line measures descent of the levator plate, and PCL measures pubococcygeal line. A, anterior; P, posterior.

Ultrasonography

Ultrasound is one of the most readily available imaging instruments to assess pelvic anatomy. Transabdominal, transperineal, transrectal, translabial, and transvaginal approaches have been used (Dietz, 2008).

Transperineal or translabial ultrasonography is often used because of its noninvasive approach and a technique that does not distort or compress many structures. The pubic symphysis, urethra, bladder neck, vagina, rectum, and anal canal are visualized routinely on translabial ultrasound. The levator plate and pubovisceral

Figure 67-19. Two-dimensional translabial ultrasound image in the midsagittal plane. B, bladder; PS, pubic symphysis; U, urethra; V, vagina.

muscles are seen as a hyperechogenic area behind the anorectal junction (Dietz, 2004). The cul-de-sac can contain fluid, fat, or small bowel. Bladder neck mobility is assessed via real-time imaging while performing a Valsalva maneuver in the supine position. Bladder wall thickness and pelvic organ prolapse can also be measured via translabial ultrasonography (Dietz, 2004). One of the other common uses of the translabial ultrasonography is to evaluate various implants such as urethral bulking agents or transvaginal mesh. Newer probes have allowed for three-dimensional imaging reconstruction to occur, which provides the added benefit of visualizing structures in the axial view rather than just the midsagittal view (Fig. 67-19).

When evaluating fecal incontinence, anorectal ultrasonography can assess for anal sphincter defects. The internal sphincter defects are seen as an echogenic discontinuity in the hypoechoic muscle between the vagina and the rectum (Hull and Zutshi, 2008). The external sphincter injury appears as a hypoechoic lesion in a normally echogenic structure. When the sphincter is in spasm or hypertrophy (as in the case of obstructed defecation), it can often have a thickened appearance (Fig. 67-20).

Endoscopic Anatomy

The caliber of the normal urethra appears to be between 14 and 20 Fr (Keegan et al, 2008). It is usually evaluated with a rigid or flexible cystoscope. The labia are spread and the urethral meatus is identified to advance the cystoscope into the urethra. The entire urethra as well as the external sphincter and bladder neck should be visualized in both a retrograde and an antegrade fashion, usually best seen with a 0-degree lens (Akorn et al, 2005). This is best performed with the irrigation flowing to distend the urethra. Great care needs to be taken to inspect the urethra, especially in women with recurrent urinary tract infections, dysuria, or obstruction. One can visualize foreign bodies, stones, and occasionally the ostia of a urethral diverticulum.

Cystoscopy allows the operator the ability to visualize the entire bladder mucosa from the dome down to the bladder neck, which is best done in a complete fashion with a 70-degree lens. The trigone and ureteral orifices are also well visualized. Often at the trigone

Figure 67-20. Endoanal ultrasound image in a normal female. EAS, external anal sphincter; IAS, internal anal sphincter.

and base of the bladder, premenopausal women can exhibit normal signs of squamous metaplasia (Clouston and Lawrentschuk, 2013). This is a nonkeratinizing metaplasia or vaginal metaplasia that is hormonally responsive and is a normal variant. Other potential findings on cystoscopy include tumors, masses, foreign bodies, fistula openings, or stones. Females of reproductive age may have an external impression at the dome of the bladder from their uterus. Bladder diverticula, cellulites, and trabeculations in women with urinary retention or obstruction can be seen on cystoscopy.

KEY POINTS: RADIOGRAPHIC ANATOMY

- MRI is the best imaging technique to visualize and differentiate anterior vaginal wall masses—especially a urethral diverticulum.
- Ultrasonography is an important imaging modality used in female pelvic medicine because of the lack of radiation and the ability to visualize almost all of the important female pelvic anatomic structures. It is also useful in visualizing foreign bodies such as bulking agents or synthetic mesh.

Bony Pelvis

Anterior Abdominal Wall

Soft Tissues of the Pelvis

Pelvic Circulation

Pelvic Innervation

Pelvic Viscera

Perineum

This chapter provides a general anatomic framework to guide the pelvic surgeon. The bony, ligamentous, and muscular framework of the pelvis is presented first. Next the pelvic vessels and nerves and the genital, urinary, and gastrointestinal viscera are discussed. Finally the perineum and external genitalia are reviewed.

BONY PELVIS

The pelvic bones are the sacrum (the termination of the axial skeleton) and the two innominate bones. The latter are formed by the fusion of the iliac, ischial, and pubic ossification centers at the acetabulum (see Fig. 67-1 in Chapter 67). The ischium and pubis also meet below, in the center of the inferior ramus, to form the obturator foramen. The weight of the upper body is transmitted from the axial skeleton to the innominate bones and lower extremities through the strong sacroiliac (SI) joints. As a whole, the pelvis is divided into a bowl-shaped false pelvis, formed by the iliac fossae and largely in contact with intraperitoneal contents, and the circular true pelvis wherein lie the urogenital organs. At the pelvic inlet, the true and false pelvis are separated by the arcuate line, which extends from the sacral promontory to the pectineal line of the pubis. The lumbar lordosis that accompanies erect posture tilts the axis of the pelvic inlet so that it parallels the ground; the pelvic inlet faces anteriorly, and the inferior ischiopubic rami lie horizontally (see Fig. 67-2 in Chapter 67). When approaching the pelvis through a low midline incision, the surgeon gazes directly into the true pelvis.

The anterior and posterior iliac spines, the iliac crests, the pubic tubercles, and the ischial tuberosities are palpable landmarks that orient the pelvic surgeon (see Fig. 67-1 in Chapter 67). Cooper (pectineal) ligament overlies the pectineal line and offers a sure hold for sutures in hernia repairs and urethral suspension procedures (Fig. 68-1). The ischial spine is palpable transvaginally and attaches to the pelvic diaphragm and the sacrospinous ligament. The sacrospinous ligament separates the greater and lesser sciatic foramina. Together with the sacrotuberous ligament, it stabilizes the SI joint by preventing downward rotation of the sacral promontory. The SI joint, synovial in type, gains additional strength from anterior and posterior ligaments. In pelvic trauma, fractures virtually never involve this joint, but they occur adjacent to it. The pubes, the thinnest of the pelvic bones, are nearly always fractured, and their fragments may injure the adjacent bladder and urethra. Resection or congenital nonunion of the pubes (e.g., bladder exstrophy) does not affect ambulation because of the strength of the SI joint (Waterhouse et al, 1973; Golimbu et al, 1990).

ANTERIOR ABDOMINAL WALL

Skin and Subcutaneous Fasciae

To minimize scarring, incisions of the anterior abdominal wall and flank should follow Langer lines of cleavage. These lines parallel dermal collagen fibers and are oriented along lines of stress. They correspond to the segmental thoracic and lumbar nerves. The skin is backed by Camper fascia, a loose layer of fatty tissue that varies in thickness with the nutritional status of the patient. The superficial circumflex iliac, external pudendal, and superficial inferior epigastric vessels branch from the femoral vessels to run in this layer (Figs. 68-2 and 68-3). The superficial inferior epigastric vessels are encountered during inguinal incisions and can cause troublesome bleeding during placement of pelvic laparoscopic ports.

Scarpa fascia forms a distinct layer deep to Camper fascia, although it may be difficult to discern in older patients. It blends superiorly and laterally with Camper fascia. It fuses inferiorly with the deep fascia of the thigh 1 cm below the inguinal ligament along a line from the anterior superior iliac spine to the pubic tubercle. Medially, it is continuous with Colles fascia of the perineum (see Fig. 68-2). Colles fascia attaches to the posterior edge of the urogenital diaphragm and the inferior ischiopubic rami. It is continuous with the dartos fascia of the penis and scrotum. These fasciae can limit both the spread of infection in necrotizing fasciitis of the scrotum (Fournier gangrene) and the extent of urinary extravasation in an anterior urethral injury. For instance, blood and urine can accumulate in the scrotum and penis deep to the dartos fascia after an anterior urethral injury. In the perineum, their spread is limited by the fusions of Colles fascia to the ischiopubic rami laterally and to the posterior edge of the perineal membrane; the resulting hematoma is therefore butterfly shaped. Because of these fasciae, bleeding, infection, or urinary extravasation will not extend down the leg or into the buttock but can freely travel up the anterior abdominal wall deep to Scarpa fascia to the clavicles and around the flank to the back.

Abdominal Musculature

The abdominal musculature lies immediately below Scarpa fascia. The origins of the external oblique, internal oblique, and transversus abdominis muscles and the orientation of their fibers are presented in Chapter 42. These muscles terminate on the anterior abdominal wall as broad, tough aponeurotic sheets that fuse in the midline (linea alba) and form the rectus sheath (see Fig. 68-3). The linea alba is avascular and is a convenient point of access

Figure 68-1. Topography (A) and posterior wall (B) of the left inguinal canal, viewed from the preperitoneal space. The location of three types of inguinal hernia is demonstrated. L, left; R, right. Figure 68-3. Muscles, vessels, and nerves of the anterior abdominal wall.

to the peritoneal and pelvic cavities. In its upper portion, the anterior rectus sheath is formed by the aponeurosis of the external oblique muscle and a portion of the internal oblique muscle (Fig. 68-4). The posterior sheath is derived from the remaining internal oblique aponeurosis and the transversus abdominis aponeurosis. At a location that is two thirds of the distance between the pubis and the umbilicus, the arcuate line is formed, as all aponeurotic layers abruptly pass anterior to the rectus abdominis, leaving this muscle clothed only by transversalis fascia and peritoneum posteriorly.

The rectus abdominis arises from the pubis medial to the pubic tubercle and inserts on the xiphoid process and adjacent costal cartilages. The muscle is crossed by three or four tendinous intersections that are firmly attached to the anterior rectus sheath; thus the muscle can be divided transversely without significant retraction. It is supplied by the last six thoracic segmental nerves that enter it laterally. Paramedian incisions lateral to the rectus

divide these nerves, cause atrophy of the rectus, and predispose to ventral hernia. Anterior to the rectus and within its sheath, the triangle-shaped pyramidalis muscle arises from the pubic crest and inserts into the linea alba (see Fig. 68-3). It is supplied by the subcostal nerve (T12).

Inguinal Canal

The inguinal canal transmits the spermatic cord and the ilioinguinal nerve in the male (Fig. 68-5; see also Fig. 68-3). The external oblique muscle, which folds over at its inferior edge as the inguinal ligament, forms its anterior wall and floor. Above the pubic tubercle, the fibers of the external oblique aponeurosis split to form the lateral edges (crura) of the external inguinal ring. Transverse (intercrural) fibers bridge the crura to form the superior edge of the external ring. By dividing the intracruial fibers, the external oblique can be separated along its fibers to gain access to the cord.

Figure 68-4. Cross section of the rectus sheath. **Top, Above the arcuate line,** the aponeurosis of the external oblique muscle forms the anterior sheath, and the transversus aponeurosis forms the posterior sheath. The internal oblique muscle splits to contribute to both the anterior and the posterior sheaths. **Bottom, Below the arcuate line,** all aponeuroses pass anterior to the rectus.

Transversalis fascia, which lines the inner surface of the abdominal wall, forms the posterior wall of the canal. The cord structures pierce this fascia lateral to the inferior epigastric vessels at the internal inguinal ring (see Fig. 68-5). The internal inguinal ring lies midway between the anterior superior iliac spine and the pubic tubercle, above the inguinal ligament, and 4 cm lateral to the external ring. Fibers of the internal oblique and transversus abdominis arise from the iliopsoas fascia and inguinal ligament lateral to the internal ring and arch over the canal to form its roof. They fuse as the conjoint tendon and pass posterior to the cord, and insert into the rectus sheath and pubis. The conjoint tendon reinforces the posterior wall of the inguinal canal at the external ring. With contraction of the internal oblique and transversus muscles, the roof of the canal closes against the floor, preventing herniation of intra-abdominal contents into the canal. Hernias into the canal may occur medial (direct) or lateral (indirect) to the inferior epigastric vessels (see Figs. 68-1 and 68-5).

Internal Surface of the Anterior Abdominal Wall

Approached laparoscopically, three elevations of the peritoneum, referred to as the **median**, **medial**, and **lateral** umbilical folds, are visible on the anterior abdominal wall below the umbilicus (Fig. 68-6). The median fold overlies the median umbilical ligament (urachus), a fibrous remnant of the cloaca that attaches the bladder to the anterior abdominal wall. The obliterated umbilical artery in the medial umbilical fold serves as an important landmark for the surgeon. It may be traced to its origin from the internal iliac artery to locate the ureter, which lies on its medial side. During transperitoneal laparoscopic pelvic lymph node dissection, the obturator packet is accessed by incising the peritoneum lateral to the

obliterated umbilical artery. In addition, during the performance of transperitoneal laparoscopic or robotic radical prostatectomy, the medial umbilical folds are used as landmarks to guide the dissection of the bladder to expose the space of Retzius. The lateral umbilical fold contains the inferior epigastric vessels as they ascend to supply the rectus abdominis.

SOFT TISSUES OF THE PELVIS

Pelvic Musculature

Muscles and fascia line the true pelvis and form its floor. The **obturator internus** arises from the inner surface of the obturator foramen and the obturator membrane and passes through the lesser sciatic foramen to insert on the femur (see Fig. 68-6). The fascia on the pelvic surface of this muscle is thickened into a tough line extending from the lower half of the pubis to the ischial spine. This tendinous arch of the levator ani serves as the origin of the muscles of the pelvic diaphragm: pubococcygeus and iliococcygeus (see Fig. 67-8 in Chapter 67). These muscles are not truly separable, and they form a diaphragm that closes the pelvic outlet. Anteriorly, a narrow U-shaped hiatus remains through which the urethra and rectum exit in the male (Fig. 68-7). The muscle bordering this hiatus has been referred to as *pubovisceral* because it provides a sling for (pubourethralis, puborectalis), inserts directly into (puboanalis, levator prostatae), or inserts into a structure intimately associated with the pelvic viscera (Lawson, 1974). The pubovisceral group provides strong fixation and support for the pelvic viscera. The coccygeus muscle extends from the sacrospinous ligament to the lateral border of the sacrum and coccyx to complete the pelvic diaphragm. Muscles of the pelvic diaphragm contain type I (slow-twitch) fibers, which provide tonic support to pelvic structures, and type II (fast-twitch) fibers for sudden increases in intra-abdominal pressure (Gosling et al, 1981). The piriformis muscle arises from the lateral aspect of the sacrum and passes through and fills the greater sciatic foramen to form the posterolateral wall of the pelvis.

It is important to recognize that the pelvic diaphragm is not flat or bowl shaped, as it is frequently depicted. At the urogenital and anal hiatus, the muscles lie in a near-vertical configuration and are thickened inferiorly (see Fig. 68-7) (Brooks et al, 1998; Myers et al, 1998). Behind the anus, they flatten to form a nearly horizontal diaphragm referred to as the *levator plate*.

Pelvic Fasciae

The pelvic fasciae are not merely collagenous; they are also rich in elastic tissue and smooth muscle. This suggests that they are active in the support, and possibly the function, of the pelvic viscera. The pelvic fasciae are continuous with the retroperitoneal fasciae and have been categorized somewhat arbitrarily into outer, intermediate, and inner strata. The outer stratum, or endopelvic fascia, lines the inner surface of the pelvic muscles and is continuous with the transversalis layer of the abdomen. It is fixed to the arcuate line of the pelvis, Cooper ligament, the sacrospinous ligament, the ischial spine, and tendinous arch of the levator ani. The intermediate stratum embeds the pelvic viscera in a fatty, compressible layer that accommodates their filling and emptying. Its tissues are easily swept aside to show the retropubic, paravesical, rectogenital, and retrorectal potential spaces. All pelvic vessels and some pelvic nerves travel in this stratum and are subject to injury when these potential spaces are developed at surgery. The intermediate stratum coalesces around vessels and nerves supplying the pelvic organs to form named ligaments (e.g., lateral and posterior vesical) that suspend and tether these organs in the pelvis. This fascia also thickens around the pelvic urogenital organs to form their visceral fascia. These are not true ligaments but are a meshwork of connective tissue and smooth muscle investing the visceral neurovascular pedicles (DeCaro et al, 1998). The inner stratum lies just beneath the peritoneum and is associated with the entire gastrointestinal tract. In the pelvis, it covers the rectum and the dome of the bladder and forms the rectogenital septum (Denonvilliers fascia). This septum

Figure 68-5. Deep structures of the left inguinal canal, viewed from the front.

is the developmental remains of the rectogenital pouch of peritoneum that extended between the rectum and the internal genitalia to the pelvic floor.

The pelvic fasciae have been given a confusing array of appellations by anatomists and surgeons. **There are three important components of the pelvic fasciae:** (1) **Anteriorly the puboprostatic ligaments** attach to the lower fifth of the pubis, lateral to the symphysis, and to the junction of the prostate and external sphincter. (2) Laterally the **arcus tendineus fasciae pelvis** extends from the puboprostatic ligament to the ischial spine. This fascia forms at the junction of the endopelvic and visceral fasciae. It should not be confused with the **arcus tendineus levator ani**, which lies above its anterior portion. In the male, the **arcus tendineus fasciae pelvis** is found at the base of a sulcus between the pelvic sidewall and the prostate and bladder. The lateral branches of the dorsal venous complex are directly beneath the **arcus tendineus fasciae pelvis**; thus the endopelvic fascia should be opened lateral to this landmark in radical prostatectomy. (3) Posterior to the ischial spine, the fascia fans out to either side of the rectum and attaches to the pelvic sidewall as the lateral and posterior vesical ligaments. The peritoneum over these ligaments forms discrete folds (rectovesical in the male) that can be appreciated at cystectomy (Fig. 68-8). Taken as a whole, the pelvic fasciae form a Y-shaped scaffolding for the pelvic viscera.

Fasciae of the Perineum and the Perineal Body

The weakest point in the pelvic floor, the urogenital hiatus, is bridged by the urogenital diaphragm, a structure unique to humans (see Fig. 68-7). The fibrous perineal membrane lies at the center of, and defines, the urogenital diaphragm (Fig. 68-9; see also Fig. 68-2). It is triangular and spans the inferior ischiopubic rami

from the pubis to the ischial tuberosities. Posteriorly it ends abruptly; the superficial and deep transverse perinei run along its free edge (Fig. 68-10). The external genitalia attach to its inferior surface; superiorly it supports the urethral sphincter (discussed later). The perineal body represents the point of fusion between the free posterior edge of the urogenital diaphragm and the posterior apex of the urogenital hiatus. This pyramid-shaped structure forms the hub of pelvic support. Virtually every pelvic muscle (superficial and deep transverse perinei, bulbocavernosus, levator ani, rectourethralis, external anal sphincter, striated urethral sphincter) and fascia (perineal membrane, Denonvilliers, Colles, and endopelvic) insert into the perineal body. At the core of the perineal body are abundant elastin and richly innervated smooth muscle, which suggests that it may have a dynamic role in support. Damage to the perineal body during perineal prostatectomy risks postoperative urinary incontinence.

PELVIC CIRCULATION

Arterial Supply

Major arteries of the pelvis are summarized in Table 68-1. At the bifurcation of the aorta, the **middle sacral artery** arises posteriorly and travels on the pelvic surface of the sacrum to supply branches to the sacral foramina and the rectum. The common iliac arteries arise at the level of the fourth lumbar vertebra, run anterior and lateral to their accompanying veins, and bifurcate into the external and internal iliac arteries at the SI joint (Fig. 68-11). The external iliac artery follows the medial border of the iliopsoas muscle along the arcuate line and leaves the pelvis beneath the inguinal ligament as the femoral artery (Fig. 68-12). Its inferior epigastric artery is given off proximal to the inguinal ligament and ascends medial to

Figure 68-6. Male pelvis and anterior abdominal wall viewed from behind. The sacrum and ilia have been removed. (From Anderson JE. *Grant's atlas of anatomy*. 7th ed. Baltimore: Williams & Wilkins; 1978.)

the internal inguinal ring to supply the rectus muscle and overlying skin. Because the rectus is richly collateralized from above and laterally, the inferior epigastric arteries may be ligated with impunity. A rectus myocutaneous flap based on this artery has been used to correct major pelvic and perineal tissue defects. Near its origin, the inferior epigastric artery sends a deep circumflex iliac branch laterally and a pubic branch medially. Both vessels travel on the iliopubic tract and may be injured during inguinal hernia repair. Its cremasteric branch joins the spermatic cord at the internal inguinal ring and forms a distal anastomosis with the testicular artery. In 25% of people, an accessory obturator artery arises from the inferior epigastric artery and runs medial to the femoral vein to reach the obturator canal. This vessel must be avoided during obturator lymph node dissection.

The internal iliac (hypogastric) artery descends in front of the SI joint and divides into an anterior and a posterior trunk (see Fig. 68-11). The posterior trunk gives rise to three parietal branches:

(1) the superior gluteal, which exits the greater sciatic foramen; (2) the ascending lumbar, which supplies the posterior abdominal wall; and (3) the lateral sacral, which passes medially to join the middle sacral branches at the sciatic foramina.

The anterior trunk yields seven parietal and visceral branches: (1) The superior vesical artery arises from the proximal portion of the obliterated umbilical artery and gives off a vesiculodeferential branch to the seminal vesicles and vas deferens. The artery of the vas deferens travels the length of the vas to meet the cremasteric and testicular arteries distally. Because of these anastomoses, the testicular artery may be sacrificed without compromising the viability of the testis. (2) The middle rectal artery gives small branches to the seminal vesicles and prostate and anastomoses with the inferior and superior rectal arteries in the rectal wall. (3) The inferior vesical branches supply the lower ureter, the bladder base, the prostate, and the seminal vesicles. (5) The internal pudendal artery leaves the pelvic cavity through the greater sciatic foramen,

Figure 68-7. Location and contour of the levator ani and pelvic viscera. **A,** Anterior view demonstrating the near-vertical orientation of the lateral walls of the levator ani and the horizontal wings at its posterior superior aspect. **B,** Lateral view in which the levator ani has been made transparent. The perineal membrane bridges the urogenital hiatus, and the urethral sphincter fills much of the hiatus. **C,** View of the levator ani from below showing the urogenital hiatus and the thickened inferior border of the levator ani. The perineal body and related structures are not shown. (From Brooks JD, Chao WM, Kerr J. Male pelvic anatomy reconstructed from the visible human data set. *J Urol* 1998;159:868-72.)

passes around the sacrospinous ligament, and enters the lesser sciatic foramen to gain access to the perineum. Its perineal course is discussed later. (6) The obturator artery, variable in origin, travels through the obturator fossa medial and inferior to the obturator nerve and passes through its canal to supply the adductors of the thigh (see Fig. 68-12). (7) The inferior gluteal artery travels through the greater sciatic foramen to supply the buttock and thigh.

The internal iliac artery can be ligated to control severe pelvic hemorrhage. Ligation decreases the pulse pressure, allowing hemostasis to occur more readily. Internal iliac blood flow does not stop but reverses its direction because of critical anastomoses (lumbar segmentals to iliolumbar; median sacral to lateral sacral; and superior rectal and middle rectal). Bilateral ligation almost invariably produces vasculogenic impotence.

Venous Supply

The dorsal vein of the penis passes between the inferior pubic arch and the striated urinary sphincter to reach the pelvis, where

it trifurcates into a central superficial branch and two lateral plexuses (Reiner and Walsh, 1979) (Fig. 68-13). To minimize blood loss at radical retropubic prostatectomy, the dorsal vein complex is best divided distally before its ramification. Part of this complex runs within the anterior and lateral wall of the striated sphincter; thus care must be taken not to injure the sphincter when securing hemostasis. The superficial branch pierces the visceral endopelvic fascia between the puboprostatic ligaments and drains the retropubic fat, the anterior bladder, and the anterior prostate (see Fig. 68-13).

The lateral plexuses sweep down the sides of the prostate, receiving drainage from it and the rectum, and communicate with the vesical plexuses on the lower part of the bladder. Three to five inferior vesical veins emerge from the vesical plexus laterally and drain into the internal iliac vein.

The internal iliac vein is joined by tributaries corresponding to the branches of the internal iliac artery and ascends medial and posterior to the artery. This vein is relatively thin walled and at risk for injury during dissection of the artery or the nearby pelvic ureter. The external iliac vein travels medial and inferior to its artery and

TABLE 68-1 Arteries of the Pelvis

ARTERY NAME	ORIGIN	SUPPLIES
Middle sacral	Aorta	Sacral nerves and sacrum
EXTERNAL ILIAC BRANCHES		
Inferior epigastric	External iliac	Rectus abdominis muscle and overlying skin and fascia
Deep circumflex iliac	Inferior epigastric	Inguinal ligament and surrounding structures laterally
Pubic	Inferior epigastric	Inguinal ligament and surrounding structures medially
Cremasteric	Inferior epigastric	Vas deferens and testis
INTERNAL ILIAC BRANCHES		
Superior gluteal	Posterior trunk	Gluteus muscles and overlying skin
Ascending lumbar	Posterior trunk	Psoas and quadratus lumborum muscles and adjacent structures
Lateral sacral	Posterior trunk	Sacral nerves and sacrum
Superior vesical	Anterior trunk	Bladder, ureter, vas deferens, and seminal vesicle
Middle rectal	Anterior trunk	Rectum, ureter, and bladder
Inferior vesical	Anterior trunk	Bladder, seminal vesicle, prostate, ureter, and the neurovascular bundle
Internal pudendal	Anterior trunk	Rectum, perineum, and external genitalia
Obturator	Anterior trunk	Adductor muscles of the leg and overlying skin
Inferior gluteal	Anterior trunk	Gluteus muscles and overlying skin

**Figure 68-8.** Peritoneal surfaces of the male pelvis. NVB, neurovascular bundle.

joins the internal iliac vein behind the internal iliac artery. In half the patients, one or more accessory obturator veins drain into the underside of the external iliac vein and can be easily torn during lymphadenectomy (see Fig. 68-12).

Pelvic Lymphatics

The pelvic lymph nodes can be difficult to appreciate on gross examination because they are embedded in the fatty and fibrous tissue of the intermediate stratum. Three major lymph node groups are associated with the pelvic vessels (Fig. 68-14). A substantial portion of pelvic visceral lymphatic drainage passes through the internal iliac nodes and their tributaries: the presacral, obturator, and internal pudendal nodes. The external iliac nodes lie lateral, anterior, and medial to the vessels and drain the anterior abdominal wall, urachus, bladder, and, in part, internal genitalia.

The external genitalia and perineum drain into the superficial and deep inguinal nodes. The inguinal nodes communicate directly with the internal and external iliac chains. The common iliac nodes receive efferent vessels from the external and internal iliac nodes and the pelvic ureter and drain into the lateral aortic nodes.

PELVIC INNERVATION

Lumbosacral Plexus

The lumbosacral plexus and its rami are well illustrated in Chapter 42; only the pelvic courses of its nerves are reviewed here (Table 68-2; see also Fig. 68-5). The iliohypogastric nerve (L1) travels between, and supplies, the internal oblique and the transversus muscles and pierces the internal and external oblique

Figure 68-9. Structure of the male striated urethral sphincter. A, Anterior projection shows the cone shape of the sphincter and the smooth muscle of the sphincter. B, Viewed laterally, the anterior wall of the sphincter is nearly twice the length of the posterior wall, although both are of comparable thickness. (From Brooks JD, Chao WM, Kerr J. Male pelvic anatomy reconstructed from the visible human data set. *J Urol* 1998;159:868–72.)

muscles 3 cm above the external inguinal ring to supply sensation over the lower anterior abdomen and pubis (see Fig. 68-3). The ilioinguinal nerve (L1) passes through the internal oblique muscle to enter the inguinal canal laterally. This nerve travels anterior to the cord and exits the external ring to provide sensation to the anterior scrotum (see Figs. 68-3 and 68-5). The genitofemoral nerve (L1, L2) pierces the psoas muscle to reach its anterior surface in the retroperitoneum and then travels to the pelvis and splits into genital and femoral branches. The latter supplies sensation over the anterior thigh below the inguinal ligament. The genital branch follows the cord through the inguinal canal, supplies the cremaster muscle, and supplies sensation to the anterior scrotum.

For most of its pelvic course, the femoral nerve (L2, L3, L4) travels within the substance of the psoas muscle and then exits its lateral side to pass under the inguinal ligament (Fig. 68-15). It supplies sensation to the anterior thigh and motor innervation to the extensors of the knee. During a psoas hitch, sutures should be placed in the direction of the nerve (and the psoas muscle fibers) to avoid nerve damage or entrapment. Retractor blades must not rest on the psoas muscle because they can produce a femoral nerve palsy, a potentially dangerous setback after pelvic surgery. The lateral femoral cutaneous nerve (L2, L3) may be seen lateral to the psoas in the iliacus fascia.

Figure 68-10. Muscles of the male perineum. The transversus perinei and ischiocavernosus frame the urogenital diaphragm. (From Williams PL, Warwick R. *Gray's anatomy*. 35th British ed. Philadelphia: Saunders; 1973.)

The obturator nerve (L2, L3, L4) emerges in the true pelvis from beneath the psoas muscle, lateral to the internal iliac vessels, and passes through the obturator foramen to the obturator canal. In the fossa, it is lateral and superior to the obturator vessels and is surrounded by the obturator and internal iliac lymph nodes. Damage to this nerve during pelvic lymphadenectomy weakens the adductors of the thigh.

The lumbosacral trunk (L4, L5) passes into the true pelvis behind the psoas and unites with the ventral rami of the sacral segmental nerves to form the sacral plexus. This plexus lies on the pelvic surface of the piriformis deep to the endopelvic fascia and posterior to the internal iliac vessels (see Fig. 68-11). It leaves the pelvis through the greater sciatic foramen immediately posterior to the sacrospinous ligament and supplies motor and sensory innervation to the posterior thigh and lower leg. An exaggerated lithotomy position may stretch this nerve or place pressure on its peroneal branch at the fibular head to produce foot drop. Pelvic and perineal branches of the sacral plexus include (1) the posterior femoral cutaneous nerve (S2, S3), which, after passing through the greater sciatic foramen, gives an anterior sensory branch to the perineum and posterior scrotum; (2) the pudendal nerve (S2, S3, S4), which follows the internal pudendal artery to the perineum (to be discussed); (3) the nervi erigentes (S2, S3, S4) to the autonomic plexus; and (4) pelvic somatic efferent nerves from the ventral rami of S2, S3, and S4 (Fig. 68-16). The latter nerves travel on the pelvic surface of the levator ani in close association with the rectum and prostate and are separated from the pelvic autonomic plexus by the endopelvic fascia. They supply the levator ani and extend anteriorly to the striated urethral sphincter (Lawson, 1974; Zvara et al, 1994).

Pelvic Autonomic Plexus

The presynaptic sympathetic cell bodies that project to the pelvic autonomic plexus reside in the lateral column of gray matter in the last three thoracic and first two lumbar segments of the spinal

Figure 68-15. Femoral nerve as it relates to the psoas muscle. Retractor blades may compress this nerve to produce a femoral nerve palsy. (From Burnett AL, Brendler CB. Femoral neuropathy following major pelvic surgery: etiology and prevention. *J Urol* 1994; 151:163–5.)

cord. They reach the pelvic plexus by two pathways: (1) The superior hypogastric plexus is formed by sympathetic fibers from the celiac plexus and the first four lumbar splanchnic nerves (Fig. 68-17). Anterior to the bifurcation of the aorta, it divides into two hypogastric nerves that enter the pelvis medial to the internal iliac vessels, anterior to the sacrum, and deep to the endopelvic fascia. (2) The pelvic continuations of the sympathetic trunks pass deep to the common iliac vessels and medial to the sacral foramina and fuse in front of the coccyx at the ganglion impar (see Fig. 68-17). Each chain comprises four to five ganglia that send branches anterolaterally to participate in the formation of the pelvic plexus.

Presynaptic parasympathetic innervation arises from the intermediolateral cell column of the sacral cord. Fibers emerge from

TABLE 68-2 Somatic Nerves of the Lower Abdomen and Pelvis

NERVE NAME	ORIGIN	SUPPLIES
Iliohypogastric	L1	Motor supply to internal oblique, transversus muscles, sensation over lower anterior abdominal wall
Ilioinguinal	L1	Sensation over anterior pubis (mons) and anterior scrotum
Genitofemoral	L1, L2	Genital branch: motor supply to cremaster muscle, sensation to anterior scrotum Femoral branch: sensation to anterior thigh
Femoral	L2, L3, L4	Motor supply to extensors of the knee, sensation to anterior thigh
Obturator	L2, L3, L4	Motor supply to adductors of the thigh, sensation to medial thigh
Lumbosacral trunk	L4, L5	Joins the sacral nerves to form the lumbosacral plexus that supplies motor and sensory innervation to the lower extremities
Posterior femoral cutaneous	S2, S3	Sensation to perineum, posterior scrotum, and posterior thigh
Pudendal	S2, S3, S4	Motor to levator ani, muscles of the urogenital diaphragm, anal and striated urethral sphincter, sensation to the perineum, scrotum, penis
Pelvic somatic efferents	S2, S3, S4	Motor supply to levator ani and striated urethral sphincter
Nervi erigentes	S2, S3, S4	Parasympathetic fibers from the sacral cord that supply the pelvic viscera

Figure 68-16. Pelvic floor somatic efferent nerves extending anteriorly on the pelvic surface of the levator ani to supply this muscle and the striated urethral sphincter. (From Lawson JO. *Pelvic anatomy. I. Pelvic floor muscles.* Ann R Coll Surg Engl 1974;54:244–52.)

the second, third, and fourth sacral spinal nerves as the pelvic splanchnic nerves (nervi erigentes) to join the hypogastric nerves and branches from the sacral sympathetic ganglia to form the inferior hypogastric (pelvic) plexus (see Fig. 68-17). Some pelvic parasympathetic efferent fibers travel up the hypogastric nerves to the inferior mesenteric plexus, where they provide parasympathetic innervation to the descending and sigmoid colon.

The pelvic plexus is rectangular, approximately 4 to 5 cm long, and its midpoint is at the tips of the seminal vesicles (Schlegel and Walsh, 1987). It is oriented in the sagittal plane on either side of the rectum and is pierced by the numerous vessels going to and from the rectum, bladder, seminal vesicles, and prostate (Fig. 68-18). Division of these vessels (the so-called lateral pedicles of the bladder and prostate) risks injury to the pelvic plexus with attendant postoperative impotence (Walsh and Donker, 1982; Walsh et al, 1983). The right and left components of the pelvic plexus communicate behind the rectum and anterior and posterior to the vesical neck. Branches of the pelvic plexus follow pelvic blood vessels to reach the pelvic viscera, although nerves to the ureter may join it directly as it passes nearby. Visceral afferent and efferent nerves travel on the vas deferens to reach the testis and epididymis.

The most caudal portion of the pelvic plexus gives rise to the innervation of the prostate and the important cavernosal nerves (Walsh and Donker, 1982). After passing the tips of the seminal vesicles, these nerves lie within leaves of the lateral endopelvic fascia near its juncture with, but outside, Denonvilliers fascia (Lepor et al, 1985). They travel at the posterolateral border of the

prostate on the surface of the rectum and are lateral to the prostatic capsular arteries and veins (see Fig. 68-18). Because the nerves are composed of multiple fibers not visible on gross inspection, these vessels serve as a surgical landmark for the course of these nerves (the neurovascular bundle of Walsh). During radical prostatectomy, the nerves are most vulnerable at the apex of the prostate, where they closely approach the prostatic capsule at the 5 and 7 o'clock positions. On reaching the membranous urethra, the nerves divide into superficial branches, which travel on the lateral surface of the striated urethral sphincter at the 3 and 9 o'clock positions, and deep fibers, which penetrate the substance of this muscle and send twigs to the bulbourethral glands. As the nerves reach the hilum of the penis, they join to form one to three discrete bundles, related to the urethra at the 1 and 11 o'clock positions, superficial to the cavernous veins and dorsomedial to the cavernous arteries (Lue et al, 1984; Breza et al, 1989). With the arteries, they pierce the corpora cavernosa to supply the erectile tissue. Small fibers also join the dorsal nerves of the penis as they course distally.

PELVIC VISCERA

Rectum

The rectum begins with the disappearance of the sigmoid mesentery opposite the third sacral vertebra. Peritoneum continues anteriorly over the upper two thirds of the rectum as the rectovesical pouch in males (Fig. 68-19). Incision of the anterior wall of this peritoneal pouch exposes the seminal vesicles behind the bladder. Inferior to this pouch, the anterior rectum is related to its fascial continuation (the rectogenital or Denonvilliers fascia) down to the level of the striated urethral sphincter (see Figs. 68-2 and 68-19). The rectum describes a gentle curve on the sacrum, coccyx, and levator plate (see Fig. 68-17) and receives innervation from the laterally placed pelvic autonomic plexus and blood supply from the superior (from inferior mesenteric), middle (from internal iliac), and inferior (from internal pudendal) rectal arteries.

The rectal wall is composed of an inner layer of circular smooth muscle and a virtually continuous sheet of outer longitudinal smooth muscle derived from the taenia of the colon. In its lowest part, the rectum dilates to form the rectal ampulla. At the most inferior portion of the ampulla, anterior fibers of the longitudinal muscle leave the rectum to join Denonvilliers fascia and the posterior striated urethral sphincter in the apex of the perineal body (Brooks et al, 2002). During perineal prostatectomy, these fibers, the rectourethralis muscle, are 2 to 10 mm thick and must be divided to gain access to the prostate (Fig. 68-20). The apices of the prostate and rectal ampulla are in close proximity, and rectal

Figure 68-17. Sympathetic and parasympathetic contributions to the pelvic autonomic nervous plexus.

injuries during radical prostatectomy commonly occur at this location. As the rectourethralis is given off, the rectum makes a right-angle turn posteroinferiorly to exit the pelvis at the anal canal (see Fig. 68-7). The anatomy of the anal canal is considered with the perineum.

Pelvic Ureter

The ureter is divided into abdominal and pelvic portions by the common iliac artery. The structure of the ureter and its abdominal course are reviewed in Chapter 42. Intraoperatively the ureter is identified by its peristaltic waves and is readily found anterior to the bifurcation of the common iliac artery. At ureteroscopy, pulsations of this artery can be seen in the posterior ureteral wall. Pyeloureterography discloses a narrowing of the ureter at the iliac vessels, and ureteral calculi frequently become lodged at this location. Because the ureter and iliac vessels rest on the arcuate line, the ureter is subject to compression and obstruction by the gravid uterus and by masses within the true pelvis.

The ureters come within 5 cm of each other as they cross the iliac vessels. On entering the pelvis, they diverge widely along the pelvic sidewalls toward the ischial spines. The ureter travels on the anterior surface of the internal iliac vessels and is related laterally to the branches of the anterior trunk. Near the ischial spine, the ureter turns anteriorly and medially to reach the bladder. In

men, the anteromedial surface of the ureter is covered by the peritoneum, and the ureter is embedded in retroperitoneal connective tissue, which varies in thickness (see Fig. 68-8). As the ureter courses medially, it is crossed anteriorly by the vas deferens and runs with the inferior vesical arteries, veins, and nerves in the lateral vesical ligaments. Viewed from the peritoneal side, the ureter is just lateral and deep to the rectogenital fold. The intramural ureter is discussed with the bladder in this chapter.

The pelvic ureter receives abundant blood supply from the common iliac artery and most branches of the internal iliac artery. The inferior vesical and uterine arteries usually supply the ureter with its largest pelvic branches. **Blood supply to the pelvic ureter enters laterally; thus the pelvic peritoneum should be incised only medial to the ureter.** Intramural vessels of the ureter run within the adventitia and generally follow one of two patterns. In approximately 75% of specimens, longitudinal vessels run the length of the ureter and are formed by anastomoses of segmental ureteral vessels. In the remaining ureters, the vessels form a fine interconnecting mesh (plexiform) with less collateral flow (Shafik, 1972). Therefore primary repair of injuries to the pelvic ureter fare poorly and are more prone to stricture formation (Hinman, 1993). Lymphatic drainage of the pelvic ureter is to the external, internal, and common iliac nodes. Pathologic enlargement of the common and internal iliac nodes can encroach on and obstruct the ureter.

Figure 68-18. Lateral view showing the left pelvic autonomic nervous plexus and its relation to the pelvic viscera. Bl, bladder; Ur, urethra. (From Schlegel PN, Walsh PC. Neuroanatomical approach to radical cystoprostatectomy with preservation of sexual function. *J Urol* 1987;138:1402–6.)

The pelvic ureter has rich adrenergic and cholinergic autonomic innervation derived from the pelvic plexus. The functional significance of this innervation is unclear, inasmuch as the ureter continues to contract peristaltically after denervation. Afferent neural fibers travel through the pelvic plexus and account for the visceral quality of referred pain from ureteral irritation or acute obstruction.

Bladder

Relationships

When filled, the bladder has a capacity of approximately 500 mL and assumes an ovoid shape. The empty bladder is tetrahedral and is described as having a superior surface with an apex at the urachus, two inferolateral surfaces, and a posteroinferior surface or base with the bladder neck at the lowest point (see Fig. 68-19).

The urachus anchors the bladder to the anterior abdominal wall (see Fig. 68-6). There is a relative paucity of bladder wall muscle at the point of attachment of the urachus, predisposing to diverticula formation. The urachus is composed of longitudinal smooth muscle bundles derived from the bladder wall. Near the

umbilicus, it becomes more fibrous and usually fuses with one of the obliterated umbilical arteries. Urachal vessels run longitudinally, and the ends of the urachus must be ligated when it is divided. An epithelium-lined lumen usually persists throughout life and uncommonly gives rise to aggressive urachal adenocarcinomas (Begg, 1930). In rare instances, luminal continuity with the bladder serves as a bacterial reservoir or results in an umbilical urinary fistula.

The superior surface of the bladder is covered by the peritoneum. Anteriorly the peritoneum sweeps gently onto the anterior abdominal wall (see Fig. 68-8). With distention, the bladder rises out of the true pelvis and separates the peritoneum from the anterior abdominal wall. It is therefore possible to perform a suprapubic cystostomy without risking entry into the peritoneal cavity. Posteriorly, the peritoneum passes to the level of the seminal vesicles and meets the peritoneum on the anterior rectum to form the rectovesical space.

Anteroinferiorly and laterally, the bladder is cushioned from the pelvic sidewall by retropubic and perivesical fat and loose connective tissue. This potential space (of Retzius) may be entered anteriorly by dividing the transversalis fascia, and it provides access to the pelvic viscera as far posteriorly as the iliac

vessels and ureters. The bladder base is related to the seminal vesicles, ampullae of the vasa deferentia, and the terminal ureter (Fig. 68-21). The bladder neck, located at the internal urethral meatus, rests 3 to 4 cm behind the midpoint of the symphysis pubis. It is firmly fixed by the pelvic fasciae (see earlier discussion) and by its continuity with the prostate; its position changes little with varying conditions of the bladder and rectum.

In infants, the true pelvis is shallow and the bladder neck is level with the upper border of the symphysis. The bladder is a true intra-abdominal organ that can project above the umbilicus when full. By puberty, the bladder has migrated to the confines of the deepened true pelvis.

Structure

The internal surface of the bladder is lined with the transitional epithelium, which appears smooth when the bladder is full but contracts into numerous folds when the bladder empties. This urothelium is usually six cells thick and rests on a thin basement membrane. Deep to this, the lamina propria forms a relatively thick layer of fibroelastic connective tissue that allows considerable distention. This layer is traversed by numerous blood vessels and contains smooth muscle fibers collected into a poorly defined muscularis mucosae. Beneath this layer lies the smooth muscle of the bladder wall. The relatively large muscle fibers form branching, interlacing bundles loosely arranged into inner longitudinal, middle circular, and outer longitudinal layers (Fig. 68-22). However, in the upper aspect of the bladder, these layers are clearly not separable, and any one fiber can travel between each of the layers, can change orientation, and can branch into longitudinal and circular fibers. This meshwork of detrusor muscle is ideally suited for emptying the spherical bladder.

Near the bladder neck, the detrusor muscle is clearly separable into the three layers described earlier. Here the smooth muscle is morphologically and pharmacologically distinct from the remainder of the bladder, for the large-diameter muscle fascicles are replaced by much finer fibers. The structure of the bladder neck appears to differ between men and women. In men, radially oriented inner longitudinal fibers pass through the internal meatus to become continuous with the inner longitudinal layer of smooth muscle in the urethra.

The middle layer forms a circular preprostatic sphincter that is responsible for continence at the level of the bladder neck (Fig. 68-23). The bladder wall posterior to the internal urethral meatus and the anterior fibromuscular stroma of the prostate form a continuous ringlike structure at the bladder neck (Brooks et al, 1998). The fact that perfect continence can be maintained in men in whom the striated urethral sphincter is destroyed attests to the efficacy of this sphincter (Waterhouse et al, 1973). This muscle is richly innervated by adrenergic fibers, which, when stimulated, produce closure of the bladder neck (Uhlenhuth, 1953). Damage to the sympathetic

Figure 68-22. Dissection of the male bladder. 11, Posterior outer longitudinal detrusor, which forms the backing of the ureters (folded back); 11a, posterolateral portion of the outer longitudinal muscle forming a loop around the anterior bladder neck; 4', 12, and 18, middle circular layer backing the trigone; 23 and 23a, lateral pedicle of the prostate. (From Uhlenhuth E. *Problems in the anatomy of the pelvis*. Philadelphia: JB Lippincott; 1953.)

nerves leading to the bladder, as a result of diabetes mellitus or retroperitoneal lymph node dissection for testis cancer, can cause retrograde ejaculation.

The outer longitudinal fibers are thickest posteriorly at the bladder base. In the midline, they insert into the apex of the trigone and intermix with the smooth muscle of the prostate to provide a strong trigonal backing. Laterally the fibers from this posterior sheet pass anteriorly and fuse to form a loop around the bladder neck (see Fig. 68-22). This loop is thought to participate in continence at the bladder neck. On the lateral and anterior surfaces of the bladder, the longitudinal fibers are not as well developed. Some anterior fibers course forward to join the puboprostatic ligaments in men. These fibers contribute smooth muscle to these supports and are speculated to contribute during micturition to the bladder neck opening (DeLancey, 1989).

Ureterovesical Junction and the Trigone

As the ureter approaches the bladder, its spirally oriented mural smooth muscle fibers become longitudinal. Two to 3 cm from the bladder, a fibromuscular sheath (of Waldeyer) extends longitudinally over the ureter and follows it to the trigone (Tanagho, 1992). The ureter pierces the bladder wall obliquely, travels 1.5 to 2 cm, and terminates at the ureteral orifice (Figs. 68-24 and 68-25). As it passes through a hiatus in the detrusor (intramural ureter), it is compressed and it narrows considerably. This is a common site in which ureteral stones become impacted. The intravesical portion of the ureter lies immediately beneath the bladder urothelium and therefore is quite pliant; it is backed by a strong plate of detrusor muscle. With bladder filling, this arrangement is thought to result in passive occlusion of the ureter, like a flap valve. Indeed, reflux does not occur in fresh cadavers when the bladder is filled (Thomson et al, 1994). Vesicoureteral reflux is thought to result from insufficient submucosal ureteral length and poor detrusor backing. (Fig. 68-26) Chronic increases in intravesical pressure resulting from bladder outlet obstruction can cause herniation of the bladder mucosa through the weakest point of the hiatus above the ureter and can produce a "Hutch diverticulum" and reflux (Hutch et al, 1961).

The triangle of smooth urothelium between the two ureteric orifices and the internal urethral meatus is referred to as the

Figure 68-23. Structure of the male bladder neck and trigone. **A**, Anterior view shows that the trigone narrows below the ureteric orifices and then widens at the bladder neck to become continuous with the anterior fibromuscular stroma of the prostate. **B**, Lateral projection shows that the trigone and anterior fibromuscular stroma are in continuity. The trigone thickens near the bladder neck as it meets the anterior fibromuscular stroma. **C**, Oblique view shows this structure at the bladder neck, where it forms the internal urethral sphincter. (From Brooks JD, Chao WM, Kerr J. Male pelvic anatomy reconstructed from the visible human data set. *J Urol* 1998;159:868–72.)

trigone of the bladder (see Fig. 68-24). The fine longitudinal smooth muscle fibers from each ureter fan out over the base of the bladder to form a triangular sheet of muscle that extends from the two ureteric orifices to the internal urethral meatus. The edges of this muscular sheet can be thickened between the ureteric orifices (the interureteric crest or Mercier bar) and between the ureters and the internal urethral meatus (Bell muscle).

The muscle of trigone forms three distinct layers: (1) a superficial layer, derived from the longitudinal muscle of the ureter, which extends down the urethra to insert at the verumontanum; (2) a deep layer, which continues from the Waldeyer sheath and inserts at the bladder neck; and (3) a detrusor layer, formed by the outer longitudinal and middle circular smooth muscle layers of the bladder wall. Through its continuity with the ureter, the superficial trigonal muscle anchors the ureter to the bladder. During ureteral reimplantation, this muscle is tented up and divided to gain access to the space between the Waldeyer sheath and the ureter. In this space, only loose fibrous and muscular connections are found. This

anatomic arrangement helps prevent reflux during bladder filling by fixing and applying tension to the ureteric orifice. As the bladder fills, its lateral wall telescopes outward on the ureter, thereby increasing intravesical ureteral length (Hutch et al, 1961).

The urothelium overlying the muscular trigone is usually only three cells thick and adheres strongly to the underlying muscle by a dense lamina propria. During filling and emptying of the bladder, this mucosal surface remains smooth.

Bladder Circulation

In addition to the vesical branches, the bladder may be supplied by any adjacent artery arising from the internal iliac artery. For convenience, surgeons refer to the vesical blood supply as the *lateral* and *posterior* pedicles, which, when the bladder is approached from the rectovesical space, are lateral and posteromedial to the ureters, respectively. These pedicles are the lateral and posterior vesical ligaments in the male (see Fig. 68-8). The veins of

Figure 68-24. Normal ureterovesical junction and trigone. **A**, Section of the bladder wall perpendicular to the ureteral hiatus shows the oblique passage of the ureter through the detrusor and also shows the submucosal ureter with its detrusor backing. Waldeyer sheath surrounds the prevesical ureter and extends inward to become the deep trigone. **B**, Waldeyer sheath continues in the bladder as the deep trigone, which is fixed at the bladder neck. Smooth muscle of the ureter forms the superficial trigone and is anchored at the verumontanum. (From Tanagho EA, Pugh RCB. The anatomy and function of the ureterovesical junction. *Br J Urol* 1963;35:151–65.)

Figure 68-25. Right ureteric orifice and right hemitrigone with scattered small calculi.

the bladder coalesce into the vesical plexus and drain into the internal iliac vein. Lymphatics from the lamina propria and muscularis drain to channels on the bladder surface, which run with the superficial vessels within the thin visceral fascia. Small paravesical lymph nodes can be found along the superficial channels. The bulk of the lymphatic drainage passes to the external iliac lymph nodes (see Fig. 68-14). Some anterior and lateral drainage may go through the obturator and internal iliac nodes, whereas portions of the bladder base and trigone may drain into the internal and common iliac groups.

Figure 68-26. Cystogram demonstrating left-sided vesicoureteral reflux into dilated ureter.

Bladder Innervation

Autonomic efferent fibers from the anterior portion of the pelvic plexus (the vesical plexus) bypass the lateral and posterior ligaments to innervate the bladder. The bladder wall is richly supplied with parasympathetic cholinergic nerve endings and has abundant postganglionic cell bodies. Sparse sympathetic innervation of the bladder has been proposed to mediate detrusor relaxation but probably lacks functional significance. A separate nonadrenergic, noncholinergic (NANC) component of the autonomic nervous system participates in activating the detrusor, although the neurotransmitter has not been identified (Burnett, 1995). As mentioned, the male bladder neck receives abundant sympathetic innervation and expresses α_1 -adrenergic receptors. The female bladder neck has little adrenergic innervation. Nitric oxide synthase-containing neurons have been identified in the detrusor, particularly at the bladder neck, where they facilitate relaxation during micturition. The trigonal muscle is innervated by adrenergic and nitric oxide synthase-containing neurons. Like the bladder neck, it relaxes during micturition. Afferent innervation from the bladder travels with both sympathetic (via the hypogastric nerves) and parasympathetic nerves to reach cell bodies in the dorsal root ganglia located at thoracolumbar and sacral levels. As a consequence, presacral neurectomy (division of the hypogastric nerves) is ineffective in relieving bladder pain.

PERINEUM

The perineum lies between the pubis, thighs, and buttocks and is limited superiorly by the levator ani. Viewed from below, the symphysis pubis, ischial tuberosities, and coccyx outline the diamond shape of the perineum; the inferior ischiopubic rami and sacrotuberous ligaments form its bony and ligamentous walls (Figs. 68-27 and 68-28; see also Fig. 68-20). A line drawn through the ischial tuberosities divides the perineum into an anal and a urogenital triangle.

Anal Triangle

At the apex of the prostate, the rectum turns approximately 90 degrees posteriorly and inferiorly to become the anus (see

Figure 68-27. Male perineum. (From Anson BJ, McVay CB. *Surgical anatomy*. 6th ed. Philadelphia: Saunders; 1984.)

Figure 68-28. Axial T1-weighted MRI of male pelvis. 1, Corpora cavernosa in cross section; 2, corpus spongiosum in cross section; 3, corpus spongiosum in perineum; 4, bulbospongiosus muscle, which facilitates urine or seminal fluid expulsion from bulbar urethra; 5, crura of corpora cavernosa—note divergence of crura as they insert on pubic bone; 6, ischial tuberosities; 7, rectum.

Figs. 68-7 and 68-9). It traverses 4 cm to reach the skin near the center of the anal triangle. The subcutaneous fat that surrounds the anus is continuous with that of the urogenital triangle, buttocks, and medial thigh. Laterally the fat fills the ischioanal fossa, a space bounded by the levator ani medially, and the obturator internus, and the sacrotuberous ligament laterally (see Fig. 68-10). Anteriorly this space extends into a recess above the urogenital diaphragm; posteriorly it is continuous with the intermediate stratum of the pelvis through the sciatic foramina. Through this continuity, infections may travel between the perineum and the pelvic cavity.

The anal sphincter is divided into internal and external components. The internal sphincter represents a thickening of the inner circular smooth muscle layer of the rectum. The outer longitudinal smooth muscle thins beyond the rectourethralis and blends with the external sphincter, although a few fibers insert in the skin around the anus (corrugator cutis ani) to produce a puckered appearance. The external sphincter surrounds the internal and is

Figure 68-29. Male perineum, illustrating the internal pudendal artery and its branches on the left and the pudendal nerve and its branches on the right.

divided into subcutaneous, superficial, and deep portions. The subcutaneous part attaches to the perineal body by collagenous and muscular fibers that are thickest superficially and are referred to as the *central tendon of the perineum*. The superficial sphincter attaches to the perineal body and coccyx. At the posterior inflection of the rectum, the deep sphincter blends with the puborectalis sling of levator ani. At this level, a firm band may be felt on rectal examination and corresponds to the internal and external sphincter. Division of this muscular band results in fecal incontinence. The prostate may be accessed anterior to the sphincter by dividing the central tendon and the sphincteric attachments to the perineum (Young procedure) or by following the anterior rectal wall beneath the external anal sphincter (Belt procedure).

Male Urogenital Triangle

The entire urogenital triangle is bridged by the urogenital diaphragm. The scrotum hangs from the anterior aspect of the urogenital triangle; in the posterior aspect, skin and subcutaneous fat overlie Colles fascia. The perineal membrane and the posterior and lateral attachments of Colles fascia limit a potential space known as the superficial pouch (see Figs. 68-2, 68-10, and 68-20). In this space, the three erectile bodies of the penis have their bony and fascial attachments (the root of the penis). The paired corpora cavernosa attach to the inferior ischiopubic rami and perineal membrane and are surrounded by the ischiocavernosus muscles. The corpus spongiosum dilates as the bulb of the penis and is fixed to the center of the perineal membrane. It is encompassed by the bulbospongiosus muscles (see Fig. 68-28) that arise from the perineal body and from a central tendinous raphe and pass around the bulb to attach to the perineal membrane and dorsum of the penis. Contraction of the ischiocavernosus and bulbospongiosus muscles compresses the erectile bodies and potentiates penile erection. The transversus perinei muscles (superficial and deep) run along the posterior edge of the perineal membrane and are thought to stabilize the perineal body. Deep to the perineal membrane rests the striated urethral sphincter (discussed earlier).

Blood supply to the anal and urogenital triangles is derived largely from the internal pudendal vessels (Fig. 68-29). After entering the perineum through the lesser sciatic foramen, the artery runs in a fascial sheath on the medial aspect of obturator internus, which is the pudendal canal (of Alcock). Early in its course, it yields

three or four inferior rectal branches to the anus. Its perineal branch pierces Colles fascia to supply the muscles of the superficial pouch and continues anteriorly to supply the back of the scrotum. The internal pudendal terminates as the common penile artery.

The internal pudendal veins communicate freely with the dorsal vein complex by piercing the levator ani. These communicating vessels enter the pelvic venous plexus on the lateral surface of the prostate and are a common, often unexpected, source of bleeding during apical dissection of the prostate. The inferior rectal veins anastomose with the middle and superior rectal veins and produce an important connection between the portal and the systemic circulation. Obstruction of the portal or systemic venous system may cause shunting of collateral venous drainage through the portal system, manifested by hemorrhoids.

The pudendal nerve follows the vessels in their course through the perineum (see Fig. 68-29). Its first branch, the dorsal nerve of the penis, travels ventral to the main pudendal trunk in Alcock canal. Several inferior rectal branches supply the external sphincter muscle and provide sensation to perianal skin. The perineal branches follow the perineal artery into the superficial pouch to supply the ischiocavernosus, bulbospongiosus, and transversus perinei muscles. A few of these branches continue anteriorly to supply sensation to the posterior scrotum. Additional perineal branches pass deep to the perineal membrane to supply the levator ani and striated urethral sphincter.

Perineal Lymphatics

The penis, scrotum, and perineum drain into the inguinal lymph nodes. These nodes may be divided into a superficial and a deep group, which are separated by the deep fascia of the thigh (fascia lata). In relation to the external pudendal, superficial inferior epigastric, and superficial circumflex iliac vessels, the superficial nodes lie at the saphenofemoral junction. At the saphenous opening (fossa ovalis) in the fascia lata, the greater saphenous vein joins the femoral vein, and the superficial nodes communicate with the deep group. Most of the deep inguinal nodes lie medial to the femoral vein and send their efferents through the femoral ring (beneath the inguinal ligament) to the external iliac and obturator nodes. Just outside the femoral ring, a large node (Cloquet or Rosenmüller node) is consistently present.

The scrotal lymphatics do not cross the median raphe and drain into the ipsilateral superficial inguinal lymph nodes. Lymphatics from the shaft of the penis converge on the dorsum and then ramify to both sides of the groin. Those of the glans pass deep to Buck fascia dorsally and drain to superficial and deep groups in

both sides of the groin. Anatomists have proposed direct lymphatic channels from the glans to the pelvic nodes, which bypass the inguinal nodes; however, clinical studies have not confirmed their existence. Other studies have suggested that all penile lymphatic drainage passes through “sentinel nodes,” which lie medial to the superficial inferior epigastric veins. Clinical studies have also called this speculation into question (Catalona, 1988). The perineal skin and fasciae drain into superficial inguinal nodes; the structures of the superficial pouch likely drain into the superficial and deep inguinal node groups.

KEY POINTS

- The pelvic cavity is divided into the false pelvis superiorly and the true pelvis inferiorly, wherein lie all of the pelvic organs.
- The bony prominences and ligaments of the pelvis and lower abdomen will orient the surgeon during physical examination and in the operating room.
- The pelvic floor is closed off by the levator ani and urogenital diaphragm and the muscles and fasciae of the pelvic floor provide critical support for the pelvic organs.
- The rectum, bladder, prostate, seminal vesicles, and penis receive blood supply from the anterior trunk of the internal iliac artery and innervation from the pelvic autonomic plexus.
- The urethra and anus exit through the perineum in association with the external genitalia.
- Detailed knowledge of the relationships of the pelvic organs to one another and to the bones and muscles of the pelvis, as well as the locations of the blood supply and innervation of all pelvic and perineal structures, is critical for performing all pelvic operations safely.

Future Research

This chapter reviews physiologic mechanisms that regulate lower urinary tract (LUT) function. The LUT is composed of the bladder and urethra, and the two defining functions of the LUT are urinary storage and emptying. Although not the focus of this chapter, another LUT function is protection of the kidneys from ascending pathogenic microorganisms, which involves appropriate functioning of the urothelium and presence of a community of microorganisms (microbiome).

Urinary storage (continence) and urinary emptying (micturition) depend on the integrated function of many components, including the central nervous system (CNS), the peripheral nervous system, bladder smooth muscle, bladder stroma, suburothelial and intradetrusor interstitial cells, bladder urothelium, urethral smooth muscle, pelvic floor striated muscles, and the external urethral sphincter (EUS). An understanding of LUT physiology is essential for management of lower urinary tract dysfunction (LUTD), such as urinary incontinence, lower urinary tract symptoms (LUTS), overactive bladder (OAB), nocturia, neurogenic bladder, and underactive bladder. Improvements in physiologic understanding will improve diagnostic and phenotyping abilities and help discover the next generation of LUTD treatments.

Laboratory investigations into LUT physiology have used animal models, and most of the data discussed in this chapter are from animal studies. This is reasonable because there are limited interventions or experiments one can do in human subjects. **However, several reasons may mitigate the relevance of animal findings to humans.** The first consideration is use of lower-order mammals (i.e., mice and rats) as a model for human LUT function. Rodents are nocturnally active and their circadian rhythm is opposite of humans. Micturition is a behavior in which some animals mark their territory, a conduct that does not apply to humans. Whereas the clinical management of LUTS is almost entirely symptom based, LUTS are difficult (if not impossible) to quantify in animals, so surrogate parameters (such as micturition frequency and volume, urodynamics) that might not relate to symptoms have been used. Another consideration is whether research data were obtained from anesthetized or awake animals, because anesthesia can alter continence and micturition reflexes. But animal models, no matter the potential drawbacks, will always be needed to improve our understanding of human LUTS. Novel findings can arise from findings in animal models (Gillespie, 2005). However, the importance of translational research, which seeks a bidirectional link between the bedside and bench, whether it is validating animal findings in humans or replicating a human phenotype in animals, is crucial in improving the treatment of LUTD.

The process of control of urinary storage and emptying is classically summarized as a complex of neural circuits in the brain and

spinal cord that coordinate the activity of smooth and striated muscles in the bladder and urethra (Torrens and Morrison, 1987; de Groat et al, 1993; Yoshimura and de Groat, 1997). These neural circuits act as switches that enable the bladder to alternate between urinary storage and elimination. Although this concept is important, translating physiologic understanding of LUT function into improved care for LUTD should be the ultimate goal. Furthermore, LUTD may not always arise from primary defects in nerves and/or muscles. Other biologic mechanisms can adversely affect LUT function, such as endocrine dysregulation (e.g., metabolic syndrome and obesity), inflammation (e.g., urothelial response to microorganisms), bladder or urethral fibrosis, and ischemia. Therefore, LUTD can be a manifestation of mechanisms arising separately from the LUT.

The mechanisms underlying control of detrusor contractility and LUT sensation remain two major areas that would benefit from continued research because of the potential for clinical impact. Many conditions encountered in LUTD relate to these two parameters. A complexity of normal LUT function is that the bladder and urethra function necessarily in an opposite manner, thus making treatments that target only the bladder or only the urethra potentially ineffective and/or causing them to have unwanted side effects. For example, treatments directed at increasing bladder contractility for detrusor underactivity may not work if the treatments do not concomitantly relax the urethra. On the other hand, an example of how a more complete understanding of a single area can improve both storage and emptying disorders is in the area of sensory (afferent) function. **Modulation of sensory mechanisms could serve two purposes: Reducing afferent signals could help those with LUTS, whereas augmenting afferent signals could help those with detrusor underactivity (Suskind and Smith, 2009; Eastham and Gillespie, 2013).** Thus, manipulation of the sensory pathway could preserve the requirement of coordinated yet simultaneously opposite bladder and urethral functions.

Although the management of LUTD is primarily symptom based at this time, use of biomarkers may come into play based on better physiologic understanding of the LUT. Ultimately, we should look forward to a time when targeted therapies and even prevention strategies may take their places in the management of LUTD patients.

LOWER URINARY TRACT ANATOMY

The bladder can be divided into several parts: a body lying above the ureteral orifices and a base consisting of the trigone and bladder neck; the two areas are different but homogeneous within

Figure 69-1. Anatomy of the bladder and its outlet, as defined by Gosling and Dixon (*left*) versus Elbadawi and coworkers (*right*). (From Torrens M, Morrison JF. *The physiology of the urinary bladder*. New York: Springer-Verlag; 1987.)

themselves regarding neuromorphology and neuropharmacology (Elbadawi and Schenk, 1966). The bladder base has a laminar architecture with a superficial longitudinal layer lying beneath the trigone (Fig. 69-1). A muscle layer deep to the superficial layer is continuous with the detrusor (Tanagho, 1982; Dixon and Gosling, 1987; Zderic et al, 1996). The smaller muscle bundles of the deep muscle layer in the bladder base exhibit a predominantly circular orientation. Histology of the full-thickness bladder is shown in Figure 69-2A. A complete and competent ring of smooth muscle at the male bladder neck has been described (Gosling, 1999). No such collar of muscle is identified in the female. The bladder neck serves an important function in reproduction. In men, closure of the bladder neck facilitates antegrade ejaculation. This is accompanied through a rich noradrenergic innervation by sympathetic nerves that actively contract the bladder neck during ejaculation. However, in women the density of adrenergic innervation in the bladder neck is reportedly less than that in men (de Groat and Booth, 1993).

The urethra is part of the bladder outlet, along with the pelvic floor musculature. The urethra has components of smooth muscle and striated muscle (rhabdosphincter or EUS) (see Fig. 69-1). The periurethral striated muscle is part of the pelvic floor muscle complex.

BLADDER COMPARTMENTS

Urothelium

The urothelium is a multilayered epithelium with a basal, intermediate, and apical layer of cells. The apical cells (umbrella cells) comprise the layer that is in contact with urine and microorganisms. The histology of the polarized urothelium is shown in Figure 69-2B; the urothelium is about seven layers thick, with the largest cells being the apical (umbrella) cells, which are sometimes multinucleated. Although the anatomy of the urothelium is relatively straightforward, there are several physiologic functions including barrier function (impermeability) and urothelial-afferent signaling, which are covered in later sections.

A scanning electron microscope (SEM) image of human apical urothelium, viewed from the luminal surface, is shown in Figure 69-3. The SEM image was obtained from a biopsy forceps cystoscopic biopsy. Note the hexagonal shape of the apical urothelial cells and the microvilli on the surface. The apical cells are also

unique in their expression of an assembly of a specialized class of proteins called *uroplakins*. The uroplakins are assembled within the apical membrane of the apical urothelial cells within specialized areas called *plaques*. The plaques have a membrane outer leaflet that is thicker than the inner leaflet, resulting in asymmetry. Thus, the plaque region is also termed the *asymmetrical unit membrane* (AUM). The areas between the plaques are symmetrical in terms of the outer and inner leaflet thickness; this area is called the *hinge region*. Inside the AUM are chainmail-like ultrastructural hexagonal particles composed of uroplakins (Fig. 69-4). These ultrastructural particles are important in barrier function. The attachment of *Escherichia coli* type 1 fimbriae to uroplakins also initiates the host-pathogen interaction, initiating a cascade of host events (Wu et al, 1996; Mulvey et al, 1998; Thumbikat et al, 2009). More details of barrier function and urothelial-afferent crosstalk of the urothelium is described in later sections.

Lamina Propria and Vasculature

The lamina propria has been recently theorized to be the “functional center” for localized control of the bladder, coordinating the activities of the urothelium and detrusor smooth muscle (Anderson and McClosky, 2014). Within the lamina propria, there is a diffuse plexus of unmyelinated nerve fibers making contact with urothelium, blood vessels, and detrusor smooth muscle. TRPV1 and P2X₃ receptors exist on nerve fibers that traverse the muscularis layer (Yiangou et al, 2001). In addition to the nerve fibers, other important structures in the lamina propria include interstitial cells (myofibroblasts) and microvasculature. The role of suburothelial myofibroblasts in detrusor contractility is discussed in a later

Figure 69-4. Hexagonal chainmail-like ultrastructural units composed of uroplakins. H, hinge area; P, plaque area. (From Kachar B, Liang F, Lins U, et al. Three-dimensional analysis of the 16 nm urothelial plaque particle: luminal surface exposure, preferential head-to-head interaction, and hinge formation. *J Mol Biol* 1999;285:595–608.)

section. These myofibroblasts positioned in the lamina propria are primed to modulate physiologic interactions between the urothelium and detrusor smooth muscle.

The anatomy of the microvasculature of the bladder in human and rabbit was studied using corrosion cast studies (Hossler and Monson, 1995; Miodoński and Litwin, 1999). The corrosion technique “fixes” the blood vessels by immediate vascular perfusion of the excised whole bladder with a fixative (e.g., a resin). Then all other tissue components of the bladder (smooth muscle, nerves, urothelium, stromal cells) were chemically digested, leaving only the vascular tree cast, which was imaged with scanning electron microscopy. The human bladder tissue studies showed a large horizontal plexus of blood vessels located in the lamina propria (termed the *mucosal plexus*) and another plexus just under the basal urothelial layer (termed the *subepithelial plexus*). Scanning electron microscopy of the mucosal vascular anatomy is shown in the Figure 69-5A, which shows a dense and rich submucosal plexus of vessels that lie immediately underneath the urothelium, the subepithelial capillary plexus. These are the vessels that would be typically seen during cystoscopy. Figure 69-5B shows a schematic of what happens to the bladder vasculature during bladder filling and emptying. Blood flow through the subepithelial plexus might also be, in part, regulated by the urothelium. Furthermore, the subepithelial plexus could play a role for substances that are transported through or secreted by the urothelium.

Because of the large increase in surface area of the bladder wall during filling, the blood vessels must be able to change length considerably. To maintain good blood flow, mechanisms may be needed to ensure that the overall resistance of the vessels, as they lengthen, does not increase sufficiently to reduce the effective perfusion of the tissue. Several groups have investigated the effects of bladder filling on the blood flow. The majority of reports have shown that the blood flow is reduced by distention (Batista et al, 1996; Greenland and Brading, 1996). In patients with low bladder compliance, there is a marked increase in the intravesicular pressure and a more pronounced decrease in bladder blood flow compared with normal controls (Ohnishi et al, 1994). The principal determinant of blood flow in the bladder wall seems to be intramural tension. During normal filling, the blood flow is able to adapt to the large increase in surface area until the pressure in the bladder increases (Greenland and Brading, 1996).

When the detrusor is deprived of oxygen or a metabolic substrate, as would occur in ischemia, its contractile ability rapidly declines (Levin et al, 1983; Zhao et al, 1991; Pessina et al, 1997; Levin et al, 2003). It has been suggested that ischemia and reperfusion might lead to damage to intramural neurons and result in the patchy denervation and altered smooth muscle function

seen in bladders of patients with detrusor overactivity (DO) (Brading, 1997a).

Stroma

The main constituents of bladder wall stroma are collagen and elastin in a matrix composed of proteoglycans. The main cells are fibroblasts. The passive mechanical properties of the bladder wall depend on the viscoelastic properties of the stroma and of the relaxed detrusor muscle (Cortivo et al, 1981). The stroma has commonly been considered a passive low-metabolic tissue that fills out the space among muscle bundles, vessels, and nerves. In recent years there has been increased appreciation for the role of the stroma in the adaptation of the bladder to pathophysiologic conditions (Macarak and Howard, 1999). Bladder hypertrophy is likely to involve an interaction of stroma and smooth muscle. In arteries, disruption of elastin in the stroma can stimulate proliferation of smooth muscle (Li et al, 1998). Although no such mechanisms are yet known in the bladder, it is possible that there could be a more intimate relationship between changes in the composition of the stroma and muscle function and growth than is appreciated at present.

Bladder Wall Collagen

Most of the bladder wall collagen is found in the connective tissue outside the muscle bundles. Changes in the relative amounts of muscle and nonmuscle tissue in the bladder wall would therefore influence collagen concentration. A number of different collagen types have been identified. In the bladder, **types I, III, and IV are the most common** (Macarak et al, 1995; Andersson and Arner, 2004). Landau and coworkers (1994) developed morphometric and histochemical techniques to determine the percentage volume of connective tissue in the bladder wall and to measure the two major types (I and III) of collagen. These methods quantitate three parameters of bladder ultrastructure: percentage volume of connective tissue, ratio of connective tissue to smooth muscle, and ratio of type III to type I collagen. These parameters have been shown to be abnormally elevated in patients with bladder disease compared with normal patients. Landau and associates further studied the ultrastructural changes that occur in the wall of dysfunctional bladders to determine the ability of new urodynamic techniques to reliably detect the clinical effect of these histologic changes. The study included 29 consecutive patients undergoing bladder augmentation. Preoperative urodynamic evaluation included measurement of the total bladder capacity, assessment of pressure-specific bladder volume, and dynamic analysis of bladder compliance. Full-thickness bladder biopsy specimens were obtained from the dome of the bladders during augmentation. The percentage of connective tissue and the ratio of connective tissue to smooth muscle were determined for all patients. These histologic results were compared with previously established normal values. All 29 patients had decreased bladder compliance, even though 9 had a normal bladder capacity. The ratio of connective tissue to smooth muscle was significantly increased in poorly compliant versus normal bladders. The ratio of type III to type I collagen was also significantly elevated. One can conclude that the poor storage function of poorly compliant bladders is secondary to an alteration in the connective tissue content of the bladder wall, especially increased collagen type III.

In the rat, infravesical obstruction or bladder denervation induces hypertrophy of the detrusor smooth muscle and, in turn, a decrease in the collagen concentration (Uvelius and Mattiasson, 1984, 1986). Aging is associated with a relative decrease in smooth muscle, in both men and women, relative to collagen content (Susset et al, 1978; Lepor et al, 1992). This could perhaps be related to the decreased packing density of submucosal collagen during aging (Levy and Wight, 1990).

Perhaps the most comprehensive work on bladder collagen was performed by Macarak and Howard (1999), who speculated that connections must exist between the tension-generating elements

(i.e., the smooth muscle cells) and the other components of the bladder. In bladders that become noncompliant (e.g., from spinal cord injury), it is likely that there is some interference with the ability of the collagen fibers to alter their tortuosity. This, predictably, would reduce total bladder capacity. Further studies are required to establish the relationship between compliance changes and the passive mechanical elements of the bladder wall that make up its structural protein matrix.

Bladder Wall Elastin and Matrix

Elastic fibers are amorphous structures composed of elastin and a microfibrillar component located mainly around the periphery of the amorphous component (Rosenbloom et al, 1995). In the mature fiber, the amorphous component makes up about 90%. The microfibrils contain a number of glycoproteins. Elastin fibers are sparse in the bladder compared with collagen but are found in all layers of the bladder wall (Murakumo et al, 1995). In spinal cord-injured rats, the elastin-to-collagen ratio increases over the first 6 weeks after injury. During this 6 weeks, the bladder compliance increases and the bladder becomes overdistended. Then the ratio is reduced as bladder compliance is decreased as a result of the emergence of DO 10 weeks after injury, suggesting a potential role for elastin in the modulation of bladder compliance (Nagatomi et al, 2005; Toosi et al, 2008).

The nonfibrillar matrix in the stroma is largely composed of a gel of proteoglycans and water. Proteoglycans are glycoproteins with glycosaminoglycans (GAGs) covalently attached. The arrangement of the proteoglycans in the matrix creates a compartment of tissue water that has a viscous behavior when it is subjected to deformation.

Smooth Muscle

Histologic examination of the bladder body reveals that myofibrils are arranged into fascicles (bundles) in random directions (Donker et al, 1982). The individual cells within a bundle are connected together to form a functional syncytium. This architecture differs from the discrete circular and longitudinal smooth muscle layers in the ureter or gastrointestinal tract.

Bladder smooth muscles have no cross striations visible under the microscope. Each detrusor smooth muscle cell contains a single nucleus. The individual smooth muscle cells in the bladder wall are small spindle-shaped cells with a central nucleus; fully relaxed, they are several hundred micrometers long with a 5- to 6- μ m maximum diameter (Smet et al, 1996). The cell membranes of smooth muscle contain caveolae—flask-shaped invaginations of the membrane—and elements of the intracellular sarcoplasmic reticulum (SR) are often associated with caveolae.

The motor innervation of the bladder smooth muscle is from the postganglionic parasympathetic nerve fibers, although intramural ganglia can exist within the bladder wall. Figure 69-6 shows the varicosities (rounded nodes) that wrap around the smooth muscle fiber. Varicosities can release a variety of neurotransmitters including acetylcholine (ACh) and adenosine triphosphate (ATP). It is unlikely that every smooth muscle cell receives direct synaptic contact; the presence of gap junctions allows excitation to propagate throughout the smooth muscle syncytium. Postjunctional receptors, such as muscarinic and purinergic receptors, are present on the smooth muscle cell. When activated by their respective agonists, these receptors initiate the excitation-contraction events (see later section) of the smooth muscle. Some investigators have found that the detrusor smooth muscle has afferent innervation that could mediate afferent signals related to smooth muscle activity (Gillespie et al, 2006).

OVERVIEW OF URETHRA

Male Urethra

The urethra begins at the bladder neck and extends to the external meatus and is composed of striated and smooth muscle. In the male, four segments are readily identified. The first is the preprostatic portion, or the bladder neck. The prostatic urethra then extends throughout the length of the gland, terminating at the prostatic apex. The membranous urethra extends from the prostatic apex through the pelvic floor musculature (including the EUS) until it becomes the bulbous and penile urethra at the base of the penis (Fig. 69-7). The male EUS covers the ventral surface of the prostate as a crescent shape proximal to the verumontanum, then assumes

Figure 69-6. Motor nerve innervation of a detrusor muscle fascicle. See text for description.

Figure 69-7. Anatomy of male urethra seen on retrograde urethrogram with patient in lateral oblique position. The red area is the external urethral sphincter, and the purple area is the prostate.

a horseshoe shape distal to the verumontanum and is crescent in shape at the bulbar urethra.

Female Urethra

In women, the urethra extends throughout the distal third of the anterior vaginal wall from the bladder neck to the meatus. Detailed anatomic descriptions of structures along the female urethra are shown in Figure 69-8. The urethra is composed of tissues that aid continence in addition to the urethral sphincter. A network of vascular subepithelial tissue in women contributes to a urethral seal effect and promotes continence. The EUS or rhabdosphincter (striated muscle) is under voluntary control and is part of the pelvic floor musculature. The female EUS covers the ventral surface of the urethra in a horseshoe configuration.

Urinary continence is maintained during elevations in intra-abdominal pressure by three processes. First, there is passive transmission of abdominal pressure to the proximal urethra. A guarding reflex involving an active contraction of striated muscle of the EUS can transiently help continence (Enhörning, 1961; Tanagho, 1982). However, mere transmission of abdominal pressure to proximal urethra does not account for the entire increase in urethral pressure (Constantinou and Govan, 1982). Urethral pressure rises before cough transmission. These findings implicate an active urethral continence (neural) mechanism in women (Constantinou and Govan, 1982). DeLancey proposed the “hammock hypothesis”—that abdominal pressure transmitted through the proximal urethra presses the anterior wall against the posterior wall. The posterior wall remains rigid if there is adequate pelvic support from muscle and connective tissues. More distally, based on morphologic data, DeLancey and colleagues (DeLancey, 1989,

Figure 69-8. Female urethra showing importance of the multiple tissues in aid of continence including striated sphincter, smooth sphincter, and subepithelial venous plexus. (From Ashton-Miller JA, DeLancey JO. Functional anatomy of the female pelvic floor. *Ann N Y Acad Sci* 2007;1101:266–96.)

1997; Sampselle and DeLancey, 1998) postulated that the urethral attachments to the pubis (pubourethral) and vaginal connections to pelvic muscles and fascia actively change the position of the bladder neck and proximal urethra with voiding. This arrangement compresses the urethra against the pubis during bladder filling and straining. These attachments contain both fascia and smooth muscle (Oelrich, 1983; DeLancey, 1988, 1989). Thus urinary continence results from the combination of active muscle tone and passive anatomic coaptation.

Anatomy Common to Both Genders

Normal pelvic dissections of human urethral sphincters during different phases of gestational development were studied anatomically (Yucel and Baskin, 2004). The findings of this study were that development of the urethral sphincteric complex is similar in both genders. The urethral complex is derived from musculature from bladder detrusor, bladder trigone, and urethral muscles, each of different embryonic origin. These investigators found that the levator ani pelvic floor muscle does not surround the ventral aspect of the urethra in either gender, and the role of the levator ani in continence was questioned.

Urethral Tone

There is controversy about the relative roles of the urethral smooth and striated circular muscles and the lamina propria in generating the urethral pressure profile, but it seems likely that both contribute (Thind, 1995). Blocking striated sphincter activity with nicotinic neuromuscular blocking agents has variable effects and may reduce urethral tone, but rarely by more than 40%, suggesting that the smooth muscles are important. Blocking sympathetic tone with α -adrenoceptor blockers may also reduce urethral pressure by about a third (Torrens and Morrison, 1987). There is little evidence for the involvement of the cholinergic innervation in generating urethral pressure.

Despite the horseshoe configuration with the open end in the posterior direction, urethral pressure recording at the external sphincter during bladder filling increases uniformly along the entire circumference like an iris (Morita and Tsuchida, 1989). Norepinephrine or hypogastric nerve stimulation augments this pressure, suggesting a role for adrenergic receptors and sympathetic nerves in the function of the EUS (Kakizaki et al, 1991).

The urethral stroma contains primarily longitudinally arranged collagen fibers and elastin fibers (Hickey et al, 1982; Huisman, 1983). The vascular filling of the urethral lamina propria is known to be of importance for urinary continence, although the magnitude of its contribution to continence is still not understood (Rud et al, 1980). Estrogen is known to increase the urethral blood flow, resulting in increased distention of the lamina propria blood vessels (Brading, 1997a).

Impaired arterial blood supply to the urethra decreases the intraluminal pressure (Rud et al, 1980), but at present it is not known whether it is the decrease in vascular filling or the urethral hypoxia that mediates the decrease in urethral pressure. It has been suggested that both these mechanisms may be involved because it was shown that the initial drop in urethral pressure was mediated through decreased vascular filling, whereas the later phase was the result of a hypoxic effect on the urethral smooth muscle (Greenland and Brading, 1996).

Results are divergent regarding the clinical significance of connective tissue outside the urethra. Paraurethral tissue biopsy specimens from premenopausal women with stress incontinence contain 30% more collagen, and the diameter of the fibrils is 30% larger than in controls (Falconer et al, 1998a). Postmenopausal stress-incontinent women, on the other hand, have no difference in collagen concentration compared with their age-matched controls (Falconer et al, 1998b). Others, however, have found a decreased periurethral collagen concentration (Rechberger et al, 1993) and a decreased ratio of collagen I to collagen III (Keane et al, 1997) in patients with stress incontinence.

Fiber Types of Urethral Striated Muscle

Striated muscles are characterized as **slow type** and **twitch type**. Twitch-type myofibrils can be further classified as **slow** and **fast** on the basis of functional and metabolic characteristics (Padykula and Gauthier, 1967). Slow-twitch fibers seem ideally suited to maintaining sphincter tone for prolonged periods, whereas fast-twitch fibers may be needed to add to sphincter tone rapidly to maintain continence when intra-abdominal pressure is abruptly increased. Similar to smooth muscle, contraction of striated muscle fibers is governed by intracellular calcium, through interactions with troponin.

The fast-twitch fibers can be recruited rapidly but also fatigue rapidly, and perform predominantly anaerobic metabolism (Markwardt and Isenberg, 1992). Fast-twitch fibers exhibit rapid bursts of contractile force and are rich in myosin ATPase that catalyzes the actin-myosin interaction. The speed of contraction may be correlated with the histochemical reaction of this ATPase and alkaline pH. In addition, fast-twitch muscles are supplied with a fast isoform of the Ca^{2+} -ATPase, which translocates the cytosolic calcium into the abundant SR to allow rapid relaxation.

In contrast, slow-twitch fibers are found in greater percentage in muscles that require sustained tension, such as the pelvic levators and urethral sphincter. These muscle fibers are recruited and fatigue slowly and can perform high rates of oxidative metabolism because they possess less of the myosin ATPase activity and contain an increased expression of a slow isoform of the Ca^{2+} -ATPase (Markwardt and Isenberg, 1992). These fibers give rise to the background electromyographic activity seen during a urodynamic evaluation.

The rhabdosphincter (EUS) is a skeletal muscle that is present in the walls of the urethra and is separate from the periurethral skeletal muscle of the pelvic floor. The muscle cells are smaller than ordinary skeletal muscle, being 15 to 20 μm in diameter. The EUS is composed of two parts. The periurethral striated muscle of the pelvic floor contains both fast-twitch and slow-twitch fibers. The striated muscle of the distal sphincter mechanism contains predominantly slow-twitch fibers (Elbadawi, 1984) and provides more than 50% of the static resistance (Tanagho et al, 1989). Gosling and colleagues (2000) presented histochemical evidence in humans that striated muscle within the distal urethra is composed primarily of slow-twitch myofibrils in contrast to the periurethral striated muscles of the pelvic floor, which contain fast-twitch and slow-twitch fibers. In the male, the rhabdosphincter consists of 35% fast-twitch and 65% slow-twitch fibers (Padykula and Gauthier, 1970). In the female, the ratio of slow-twitch to fast-twitch fibers is 87% slow-twitch and 13% fast-twitch fibers.

The majority of the fast-twitch fibers and about a fourth of the slow-twitch fibers in the intramural striated muscle of the human membranous urethral sphincter show positive staining for nitric oxide (NO) synthase (NOS) in the sarcolemma (Ho et al, 1998). Moreover, the striated periurethral muscles of the pelvic floor are adapted for the rapid recruitment of motor units required during increases in abdominal pressure. It has been speculated that the successful treatment of stress incontinence by pelvic floor exercises or electrostimulation is caused by the conversion of fast-twitch to slow-twitch striated muscle fibers (Bazeed et al, 1982).

In addition to striated muscle, the external sphincter appears to contain smooth muscle, which receives noradrenergic innervation. Investigators have shown that stimulation of the hypogastric nerve elicits myogenic potentials in the EUS (Kakizaki et al, 1991). Whether this activity is the result of smooth or striated muscle is unclear. Because these potentials persist after α -adrenergic blockade, investigators postulate that the activity arises from striated muscle.

UROTHELIAL PHYSIOLOGY

Although the primary role of the urothelium is to form a relatively impermeable barrier to protect the underlying stroma of the bladder,

other roles of the bladder urothelium include sentinel defense against uropathogenic bacterial infections, afferent signaling, and modulation of detrusor smooth muscle contractility.

Barrier Function

Epithelial permeability, including that of the urothelium, depends on a number of factors. These are passive diffusion, osmotically driven diffusion, active transport, and inertness of the membrane to the solutes to which it is exposed.

Descriptions of finite passage of substances across the urothelium are well known. In 1856, Kaupp reported that the composition and volume of urine were altered with 12-hour voiding patterns instead of hourly voiding. These changes in volume have also been noted in rats during isovolumetric cystometrograms during 3-hour periods (Sugaya et al, 1997), and the rate of water loss has also been estimated by direct measurement of passive water diffusion in vitro in the rabbit (Negrete et al, 1996). There is a passive permeability to most substances in the blood or urine (Hicks, 1975). In studies using an in vivo rat model, the bladder urothelium was permeable to urea, sodium, potassium, and chloride (Spector et al, 2011, 2013). The authors of these studies contend that the bladder modifies the final urinary concentration of these solutes and that this modification depends on the hydration status and dietary protein (Spector et al, 2012).

The human bladder urothelium is also permeable to water, because of expression of the water transport protein aquaporin (Rubenwolf et al, 2009, 2012). Water permeability value in humans was measured at 6.5×10^{-5} cm/sec (Fellows and Marshall, 1972). This value was obtained by estimating the absorption of tritiated water into the plasma after instillation of the tritiated water into the bladder of volunteers. A direct measurement of urothelial diffusive permeability in the human has not yet been made. A measurement tool may help better phenotype LUTD that might be associated with increased urothelial permeability.

Breakdown of the apical (umbrella) cells in animal models of cystitis has shown increased water and urea permeability. Presumably, leakage of urinary solutes into the lamina propria is also responsible for the symptoms of cystitis (Lavelle et al, 1998, 2000). This increase in urothelial permeability with cystitis is increased further by distention of the bladder. The hypothesis is that with distention of the bladder, the weakened urothelium with denuded

apical umbrella cells and no real barrier in the intermediate or basal cells is further disrupted, thus allowing further egress of urine constituents into the detrusor. Similar breakdown of the apical cells is thought to occur in most forms of infectious cystitis and also in radiation cystitis.

Direct measurements of the osmotic effect on permeability have not been performed on urothelium. However, the urothelium maintains an osmotic gradient between plasma (approximately 300 mOsm/kg) and urine (100 to 1500 mOsm/kg), depending on the level of water balance and diuresis of the individual. In the normal bladder, the osmotic effects of the urine appear to go unnoticed, and the patients have few or no symptoms. However, once the bladder is inflamed, as in bladder pain syndrome and interstitial cystitis (BPS/IC), the effects of osmotic gradients become important (Gao et al, 1994).

Patients with spinal cord injury or with myelodysplasia tend to have chronic cystitis with bacteriuria and inflamed urothelium. When detrusor activity was increased in the rat by instillation of hyperosmolar compounds, this was accompanied by neurogenic inflammation, including plasma extravasation of Evans blue that could be decreased by pretreatment with the C-fiber afferent neurotoxin capsaicin (Maggi et al, 1990), indicating that hyperosmolar solutions excite afferent nerves. With increased osmolality, detrusor contractions were much stronger and accompanied by blood pressure elevations. These effects were enhanced when the bladder was pretreated with dimethyl sulfoxide to simulate cystitis conditions (Hohlbrugger and Lentsch, 1985; Hohlbrugger, 1987).

Tight junction (TJ) proteins also contribute to the impermeability of the bladder urothelium. TJ proteins include zona occludens-1 (ZO-1), occludin, claudin-4, claudin-8, and claudin-12 (Acharya et al, 2004). TJs are present between cells to prevent paracellular (between the cell) permeability (Fig. 69-9). These TJ proteins adapt to stretch of the urothelium during filling and voiding without affecting permeability (of small molecules biotin, fluorescein, and ruthenium red), although there was a 10-fold drop in transepithelial resistance (TER) during urothelial stretch (Carattino et al, 2013). This drop in TER reflected increased ionic paracellular transport via claudin permeation pathway. In addition to these physiologic functions (barrier function, host response to pathogens) of the urothelium, the roles of urothelial-afferent signaling and modulation of smooth muscle contractility are covered in later sections.

Figure 69-9. Junctional complexes between cells include tight junctions, adherens, desmosomes, and gap junctions. Gap junctions include proteins such as zona occludens and claudins.

The GAG layer, which has been described to be located on the luminal surface of the apical urothelial cell, has been a controversial subject of research into urothelial barrier function. GAG refers to a structure composed of 100% carbohydrate (polysaccharide). GAG is not produced through a template reaction as a protein is (DNA → RNA → protein), but rather through a series of enzymatic reactions within the cell. For this reason, GAG can be highly heterogeneous in molecular weight and composition. This GAG theory arose from findings of increased bacterial adherence to rabbit bladder urothelium after topical acid treatment and return to normal function with decreased adherence within 24 hours after acid injury, suggesting a “secretory” factor produced by the urothelium protecting the urothelium against bacterial adherence (Parsons et al, 1975). The secretory factor was reported to be GAG, based on the histology of rabbit bladders (Mulholland et al, 1976). However, using a different approach, it was found that the secretory factor was a glycoprotein (mucin glycoprotein MUC-1) rather than a polysaccharide (GAG) (Buckley et al, 1996; Higuchi et al, 2000). In an indirect method of examining the role of the GAG layer, Madin-Darby canine kidney (MDCK) cells were transfected with MUC-1. After this treatment, no difference in the transcellular water and urea permeability was found (Lavelle et al, 1997). Immunofluorescence study of human urothelium showed that chondroitin sulfate was the main GAG component, although the role of GAG in creating impermeability was studied in monolayer of cultured pig urothelial cells (Janssen et al, 2013). In summary, the GAG layer may have importance in bacterial antiadherence and in prevention of urothelial damage by large macromolecules. However, there is no definite evidence that the GAG layer acts as the primary epithelial barrier between urine and plasma in the human urothelium.

Ionic Transport

The apical membrane of the urothelium has a high electrical resistance (Lavelle et al, 1998, 2000), whereas the basolateral membrane resistance is approximately 10-fold lower (Clausen et al, 1979). Active sodium transport across the urothelium has been demonstrated (Wickham, 1964; Lewis and Diamond, 1976). Na⁺ channels that exist on the apical surface of the umbrella cells and in the cytoplasmic vesicles below the apical surface are primarily amiloride sensitive (inhibition) and aldosterone responsive. However, amiloride-insensitive, cation-selective, as well as amiloride-insensitive, unstable cation channels have also been identified. Both of these channels were found to be degradation products of the amiloride-sensitive Na⁺ channel. The amiloride-sensitive Na⁺ channel is hydrolyzed by serine proteases such as kallikrein and urokinase and plasmin (normally found in the urine but produced by the kidney) (Lewis et al, 1995). Studies of rat bladders have shown that urea, sodium, potassium, and chloride can all cross the bladder urothelium and be taken up by suburothelial blood vessels (Spector et al, 2011, 2012, 2013).

Sodium that is transported into the cell is removed at the basolateral membrane by an Na⁺-K⁺ exchanger. This leaves the cell with a negative intracellular charge. The basolateral membrane contains K⁺ and Cl⁻ channels, Na⁺-H⁺ exchangers, and Cl⁻-HCO₃⁻ exchangers. These channels and exchangers are important in recovery of cell volume during an increase in serosal osmolality (Donaldson and Lewis, 1990). Unfortunately, the precise role of the Na⁺ channel in the apical membrane of the umbrella cell is unknown. It is possible that the degradation of the channel might follow the filling of the bladder and that the changes in conductance of sodium may be a signaling factor for the bladder and micturition when it reaches capacity. Alternatively, it may be involved in the signaling pathway that allows insertion or removal of apical membrane on expansion of the bladder.

Sensor-Transducer Function of the Urothelium

Whereas the urothelium has historically been viewed primarily as a barrier, there is increasing evidence that urothelial cells display a number of properties similar to sensory neurons (nociceptors

and mechanoreceptors) and that both types of cells use diverse signal-transduction mechanisms to detect physiologic stimuli. Examples of “sensor molecules” (i.e., receptors and ion channels) associated with neurons that have been identified in urothelium include receptors for bradykinin (Chopra et al, 2005), neurotrophins (TrkA and p75) (Murray et al, 2004), purines (P2X and P2Y) (Lee et al, 2000; Hu et al, 2002; Birder et al, 2004; Sun and Chai, 2004; Tempest et al, 2004; Chopra et al, 2008), norepinephrine (α and β) (Birder et al, 1998, 2002), ACh (nicotinic and muscarinic) (Chess-Williams, 2002; Beckel et al, 2006; Kullmann et al, 2008b), protease-activated receptors, amiloride-mechanosensitive Na⁺ channels such as ENaC (Smith et al, 1998; Wang et al, 2003; Araki et al, 2004), and a number of TRP channels (TRPV1, TRPV2, TRPV4, TRPM8) (Birder and de Groat, 1998; Birder et al, 2001, 2002; Stein et al, 2004; Birder et al, 2007a; Gevaert et al, 2007).

When urothelial cells are activated through these receptors and ion channels in response to mechanical as well as chemical stimuli, they can, in turn, release chemical mediators such as NO, ATP, ACh, and substance P (SP) (Ferguson et al, 1997; Birder et al, 1998; Burnstock, 2001a; Birder et al, 2003; Chess-Williams, 2004). These agents are known to have excitatory and inhibitory actions on afferent nerves that are close to or in the urothelium (Bean et al, 1990; Dmitrieva et al, 1998; Birder et al, 2001; Yoshimura et al, 2008). A video of urothelial cells responding to increasing doses of extracellular carbachol, a nonselective muscarinic agonist, with increasing concentrations of intracellular Ca²⁺ (fura-2 ratio), is shown in the microfluorometry video on the Expert Consult website.

Chemicals released from urothelial cells may act directly on afferent nerves or indirectly through an action on suburothelial interstitial cells (also referred to as myofibroblasts) that lie in close proximity to afferent nerves. Myofibroblasts are extensively linked by gap junctions and can respond to chemicals that in turn modulate afferent nerves (Fowler et al, 2008). Thus it is believed that urothelial cells and myofibroblasts can participate in sensory mechanisms in the urinary tract by chemical coupling to the adjacent sensory nerves.

NO can be released by the urothelium, particularly during inflammation (Birder et al, 1998). The release of NO may be evoked by the calcium ionophore A-23187, norepinephrine, and capsaicin. SP also acts on receptors on urothelial cells to release NO. The adrenergic release of NO from bladder strips was reduced by 85% after removal of the urothelium. Denervation of the bladder did not completely block the release of capsaicin-induced NO production, suggesting other sites of production. This is consistent with the observations that capsaicin released NO from cultured rat, cat, rabbit, and human urothelial cells and that the TRPV1 capsaicin receptor is expressed in cultured urothelial cells. NOS expression in afferent neurons is also increased in chronic bladder inflammation. Given that NO does not have much effect on the detrusor muscle but does inhibit Ca²⁺ channels in rat bladder afferent neurons (Yoshimura et al, 2001), the role of NO in the urothelium has still to be clarified. However, NO released locally in the bladder appears to have an inhibitory effect on afferent activity in the bladder because suppression of endogenous NO by intravesical oxyhemoglobin, an NO scavenger, or L-NAME, a NOS inhibitor, enhances bladder activity in rats (Pandita et al, 2000; Masuda et al, 2007).

ATP released from urothelial cells during stretch can activate a population of suburothelial bladder afferents expressing P2X₃ receptors, signaling changes in bladder fullness and pain (Ferguson et al, 1997; Burnstock, 2001a). Accordingly, P2X₃ null mice exhibit a urinary bladder hyporeflexia, suggesting that this receptor, as well as neural-epithelial interactions, are essential for normal bladder function (Cockayne et al, 2000). This type of regulation may be similar to epithelium-dependent secretion of mediators in airway epithelial cells, which are thought to modulate submucosal nerves and bronchial smooth muscle tone and may play an important role in inflammation (Homolya et al, 2000; Jallat-Daloz et al, 2001). Thus it is possible that activation of bladder nerves and urothelial cells can modulate bladder function directly or indirectly

by the release of chemical factors in the urothelial layer. ATP released from the urothelium or surrounding tissues may also play a role in the regulation of membrane trafficking. This is supported by studies in the urinary bladder in which urothelium-derived ATP release purportedly acts as a trigger for exocytosis, in part by autocrine activation of urothelial purinergic (P2X, P2Y) receptors (Wang et al, 2005). These findings suggest a mechanism whereby urothelial cells sense or respond to ATP and thereby translate extracellular stimuli into functional processes.

A study showed that human bladder urothelial tissue behaved similarly to guinea pig bladder urothelium. Both urothelia released ATP in response to both muscarinic and purinergic stimulation (Sui et al, 2014). The released ATP induced contraction of the urothelial mucosal tissue. Aging was associated with increased ATP release. These findings continue to support the hypothesis that the urothelium is capable of sensing and transducing signals and likely modulates overall bladder function.

Prostaglandins are also released from the urothelium. These are assigned two possible functions: regulation of detrusor muscle activity and cytoprotection of the urothelium, based on effective treatment of hemorrhagic cystitis by prostaglandins (Jeremy et al, 1987). The predominant forms found in human urothelium from biopsy specimens are 6-oxo-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) more than PGE_2 more than $PGF_{2\alpha}$ more than thromboxane B_2 , PGL_2 (prostacyclin) is also produced. These findings were confirmed and further developed in the guinea pig, in which it was found that the major production of prostaglandins occurred in the urothelium. The production of prostaglandins also increased greatly with inflammation (Saban et al, 1994). Prostaglandin synthesis also occurs in the ureter, where it is speculated to be important in the regulation of ureteral peristalsis and also in reducing the development of blood clots in the lumen of the ureter (Ali et al, 1998).

Evidence also suggests that the involvement of the muscarinic receptor in bladder function extends beyond detrusor contractility and into afferent sensory functioning. Muscarinic receptors are found on the urothelium at high density (Hawthorn et al, 2000), and there is a basal release of ACh from the urothelium that is increased by stretch and aging (Yoshida et al, 2006). Thus activation of the muscarinic receptors in the urothelium releases substances that modulate afferent nerves and smooth muscle activity (Hawthorn et al, 2000; de Groat, 2004; Kullmann et al, 2008a).

The urothelium also releases substances called **urothelium-derived inhibitory factors**, which decrease the force of detrusor muscle contraction in response to muscarinic stimulation (Hawthorn et al, 2000; Kumar et al, 2005). The molecular identity of this factor is not known; however, pharmacologic studies suggest that it is not NO, a prostaglandin, prostacyclin, adenosine, catecholamine, γ -aminobutyric acid (GABA), or a factor that acts through apamine-sensitive, small-conductance K^+ channels. It has been shown that an inhibitory response through this factor is attenuated in a fetal model of bladder outlet obstruction (BOO) (Thiruchelvam et al, 2003). Further studies are required to clarify the identity of this substance and its role in bladder function.

Suburothelial Interstitial Cells

In the human bladder, subepithelial interstitial cells, which are also called **myofibroblasts**, are located just below the basal layer of the urothelium. These myofibroblasts stain for vimentin and α -smooth muscle actin but not for desmin (Fry et al, 2004). These cells are linked by gap junctions consisting of connexin 43 (Cx43) proteins and make close appositions with C-fiber nerve endings in the submucosal layer of the bladder, suggesting that there is a network of functionally connected interstitial cells immediately below the urothelium that may be modulated by other nerve fibers (Fry et al, 2004) (Fig. 69-10). ATP can induce inward currents associated with elevated intracellular Ca^{2+} in isolated suburothelial interstitial cells (Fry et al, 2007).

Immunohistochemical studies show the expression of P2Y receptors, most notably P2Y₆ receptors, and M₃ muscarinic receptors

Figure 69-10. Schematic representation of suburothelial interstitial cells, which are also called **myofibroblasts**. Substances released from the basolateral surface during stretch, such as adenosine triphosphate (ATP) and acetylcholine (ACh), activate afferents in the suburothelial layer through the intermediation of suburothelially located interstitial cells, which express purinergic P2Y receptors, muscarinic M₂ and M₃ receptors, or capsaicin TRPV1 receptors, and are connected to one another by gap-junction proteins.

in suburothelial interstitial cells from guinea pigs (Fry et al, 2007; Grol et al, 2009). In the human bladder, increased expression of muscarinic M₂ and M₃ receptors in vimentin-stained suburothelial interstitial cells is found and correlates with the urgency score in humans with idiopathic detrusor overactivity (IDO) (Mukerji et al, 2006). Because ATP or ACh is known to be released from the urothelium during bladder stretch, suburothelial interstitial cells are in an ideal position between the urothelium and nerve endings to modify a sensory feedback mechanism. Application of an NO donor sodium nitroprusside (SNP) also attenuates an increase in intracellular Ca^{2+} and current responses to ATP in guinea pig interstitial cells, suggesting the cyclic guanosine monophosphate (cGMP)-dependent inhibition of cell activity (Sui et al, 2008).

KEY POINTS: UROTHELIUM

- Uroplakin proteins and TJ proteins play key parts in urothelial barrier function.
- Uroplakins have also been shown to act as the primary attachment site of type 1 piliated uropathogenic *E. coli*.
- The GAG layer may have importance in bacterial antiadherence, but there is no definite evidence that the GAG layer serves impermeability function.
- Urothelial cells can release and respond to neurotransmitters.
- Myofibroblasts mediate interaction between urothelial cells and afferent nerves.

SMOOTH MUSCLE PHYSIOLOGY

Studies on bladder smooth muscle physiology have been a mainstay for understanding micturition function, because the detrusor smooth muscle needs to contract for the bladder to empty efficiently and normally. Understanding the factors that regulate smooth muscle quiescence could be applicable to clinical conditions characterized by DO such as OAB, neurogenic bladder, and

TABLE 69-1 Comparison of the Properties of Skeletal and Smooth Muscle

PROPERTY	SKELETAL MUSCLE	SMOOTH MUSCLE
Cell characteristics	Long cylindric cells with many nuclei	Spindle-shaped cells with a single nucleus
Maximum cell size (length × diameter)	30 cm × 100 μm	200 μm × 5 μm
Visible striations	Yes	No
Ultrastructure	Sarcomere pattern No immediate filaments	No sarcomere pattern Intermediate filaments Dense bodies
Motor innervation	Somatic	Autonomic
Type of contracture	Phasic	Mostly tonic, some phasic
Contractile activity	Disinhibition of tropomyosin Sliding filaments Rapid contraction	Active myosin phosphorylation ? Sliding filaments Formation of “latch state”
Calcium regulation	Rapid Ca ²⁺ influx via T tubule	Voltage- and receptor-operated Ca ²⁺ channels Release from internal stores
Basic muscle tone	Neural activity	Intrinsic, extrinsic factors
Force of contraction regulated by hormone	No	Yes

underactive detrusor. Function of the smooth muscle, like striated muscle, is regulated by motor nerves (though autonomic rather than somatic), but unlike striated muscle, smooth muscle function can be also be modulated by circulating hormones, local paracrine factors such as NO, and factors released by the urothelium. Although the coordinated and efficient contractions of the detrusor smooth muscle require neural control, detrusor muscle can generate spontaneous and rhythmic activity without neural input. The differences between smooth muscle versus striated muscle properties are shown in Table 69-1 (Chacko et al, 1999). The next several sections will cover physiologic aspects of detrusor smooth muscle function starting at the individual smooth muscle cell and moving to the whole organ level.

Contractile Proteins

Bladder (detrusor) smooth muscle cells contract by the interaction of thick and thin filaments within the intracellular cytoskeletal network. Thick filaments (15-nm diameter) are composed of myosin. Thin filaments (6- to 8-nm diameter) are composed mainly of actin. Bound to actin are tropomyosin (TM) and caldesmon (CaD), both of which are important in regulation of contraction. Intermediate filaments (10 nm in diameter) are composed of desmin and vimentin. Whereas contraction of smooth muscle cells is caused by the cross-bridge cycling between the thick and thin filaments, intermediate filaments can modulate the contractile response (see review by Tang, 2008). The thin and thick filaments of smooth muscle fibers are arranged as myofibrils that cross the fibers obliquely in a lattice-like arrangement, rather than the organized linear fashion of the sarcomere in striated muscle fibers. The thin and intermediate filaments attach to multiple sites within the cytoplasm (sarcolemma) at locations called *dense bodies* (Fig. 69-11). The filaments of contractile proteins are also attached to the plasma membrane at junctional complexes between neighboring cells, which allow smooth muscle cells to contract as a syncytium.

Thick filaments are made up of myosin II—two intertwined myosin heavy chains (MHCs) (Fig. 69-12) (as opposed to myosin I, which contains only one MHC). There are two areas of myosin II: the rod portion, which contains the coil region, and the head region, which contains globular domains of the two MHCs, with an intervening hinge region between the coil and head. Alternative splicing of MHCs pre-mRNA at the 5'-end produces SM-A and SM-B isoforms of MHC, whereas alternative splicing at the 3'-end produces SM-1 and SM-2 isoforms of MHC. The bladder smooth

Figure 69-11. The organization of the contractile elements of smooth muscle fibers by a simple model of the contraction of smooth muscle. **A**, Relaxed smooth muscle cell. **B**, Contracted smooth muscle cell. Intermediate filaments, dense bodies, and dense bands of smooth muscle fibers harness the pull generated during myosin cross-bridge activity. Intermediate and thin filaments attach to dense bodies scattered throughout the sarcoplasm and occasionally anchor to the dense bands situated between caveolae (invaginations of the sarcolemma). As the obliquely running contractile elements contract, the muscle shortens.

muscle contains almost 100% SM-B. SM-B has a higher ATPase activity than SM-A; therefore SM-B can move actin filaments faster in an in vitro assay (Rovner et al, 1997).

Contained within each globular region of the MHC are two myosin light chains (MLCs), MLC20 (20 kDa) and MLC17 (17 kDa). These two MLC isoforms are encoded by different genes, but only one relates to contractility. Two MLC17 variants occur as a result of alternative splicing of a single MLC17 gene. Cross-bridge cycling depends on the phosphorylation of MLC20, which increases the activity of an enzyme, myosin ATPase.

Although studies of interactions between actin and myosin in cross-bridge cycling have been canonical in understanding smooth muscle contractility, the unique role of actin has been only recently recognized and reviewed (Gunst and Zhang, 2008). The structure and organization of filamentous actin was thought to remain relatively constant during a contractile event. Furthermore, it was assumed that actin filaments anchored at adhesion sites at the plasma membrane and at dense bodies within the cytosol (see Fig. 69-11), which provides a fixed and stable network on which the myosin or thick filaments move during shortening and tension development. However, intracellular actin polymerization is now

recognized as a seminal event in smooth muscle contraction. This actin polymerization further serves to catalyze recruitment of structural proteins that connect actin filaments and transmembrane integrin proteins to adhesion junctions (Fig. 69-13).

The interaction between actin and myosin in smooth muscle contractions is modulated by the actin-binding (actin-associated) proteins caldesmon (CaD) and tropomyosin (TM) (Fig. 69-14). These two proteins control access points on the actin filament to allow myosin II heads to form cross-bridges. Figure 69-14 shows that CaD interacts with all of the contractile proteins and also calmodulin (CaM). CaD was first isolated from chicken gizzard smooth muscle in 1981 (Sobue et al, 1981). There are two isoforms of CaD: heavy CaD (h-CaD), which is associated with all smooth muscle, and light CaD (l-CaD), which is found in non-smooth muscle cells. CaD is an inhibitor of actinomyosin ATPase and motility, and both actin binding and CaD inhibition are greatly enhanced in the presence of TM. Detailed descriptions of CaD functions have been reviewed (Wang, 2008). CaD is modulated by another protein, CaM. Although CaM is technically not a contractile protein, CaM is the protein that interacts with intracellular Ca^{2+} to initiate the contraction.

Actinomyosin Cross-Bridge Cycling

The key step in smooth muscle cellular contraction is cross-bridge formation of myosin II heads to actin, which is dependent on rise of intracellular Ca^{2+} . When an action potential (AP) occurs in the smooth muscle cell, there is a rise in intracellular Ca^{2+} , which then binds to CaM, thereby activating myosin light chain kinase (MLCK) (Hai and Murphy, 1989; Gunst et al, 1993;

Figure 69-12. Structure of myosin II, composed of two intertwined myosin heavy chains (MHCs). MLC17 and MLC20 are two myosin light chains located on heads of myosin II.

Figure 69-13. Figure shows a single myocyte going from relaxation to contraction. The importance of actin polymerization at the periphery of the cell is that this network strengthens the membrane for force transmission from the actinomyosin cross-bridges. The regulation of actin polymerization is distinct and separate from actinomyosin cross-bridge cycling. (From Gunst SJ, Zhang W. Actin cytoskeletal dynamics in smooth muscle: a new paradigm for the regulation of smooth muscle contraction. *Am J Physiol Cell Physiol* 2008;295:C576–87.)

Andersson and Arner, 2004). MLCK phosphorylates MLC20, which is in the head region of myosin II, cleaving a phosphate moiety in ATP, thus converting ATP to adenosine diphosphate (ADP) in the process. Phosphorylated MLC20 forms cross-bridges with (i.e., binds to) actin, leading to force generation (White et al, 1993; Chacko et al, 1994; Andersson and Arner, 2004). Dephosphorylation of MLC20 is catalyzed by myosin light chain phosphatase (MLCP), leading to detachment of the myosin II heads from actin and relaxation. An animation of these interactions is shown on the Expert Consult website. Key points in the smooth muscle contraction sequence are also presented in Box 69-1.

Figure 69-14. Caldesmon (CaD) and tropomyosin are actin-bound proteins that regulate actinomyosin cross-bridging. CaD and tropomyosin move along the actin filament to expose actin binding sites for the head region of myosin II to generate contraction. (From Shirinsky VP, Vorotnikov AV, Gusev NB. Caldesmon phosphorylation and smooth muscle contraction. In: Kohama K, Sasaki Y, editors. Molecular mechanisms of smooth muscle contraction. Austin [TX]: R.G. Landes Company; 1999.)

The determination of smooth muscle tone is therefore dependent on the balance of intracellular Ca^{2+} and the balance between MLCK and MLCP activities. Although Ca^{2+} is needed for MLCK activity, regulation of MLCP activity plays an important role in smooth muscle contractility. **Inhibition of MLCP activity promotes contractility and tone in the smooth muscle cell in the absence of increases in intracellular Ca^{2+} changes (calcium sensitization).** It has been shown that MLCP activity is under control of a series of complex molecular events related to two proteins, RhoA and Rho kinase (ROK).

RhoA is part of a family of proteins known as *small GTPases*. The activity of RhoA (active vs. inactive forms) is based on the form of guanine phosphate bound to RhoA. Inactive RhoA is bound to guanosine diphosphate (GDP) (Rho-GDP), and active RhoA is bound to guanosine triphosphate (GTP) (Rho-GTP). Three classes of regulatory proteins control the cycling between active RhoA and inactive RhoA forms: (1) guanine nucleotide exchange factors (GEFs), which convert RhoA-GDP to Rho-GTP; (2) GTPase-activating proteins (GAPs), which convert Rho-GTP to Rho-GDP; and (3) guanine nucleotide dissociation inhibitors (GDIs), which bind to RhoA-GDP and prevent action of GEFs and prevent RhoA-GDP from translocating from cytosol to cellular membrane, which inhibits the activity of RhoA (Puetz et al, 2009).

Activated RhoA, RhoA-GTP, binds to ROK at the cellular membrane to activate ROK. Activated ROK phosphorylates MLCP, inactivating MLCP, thus tipping the balance toward contraction of the smooth muscle cell. Another mechanism in which activated ROK can inactivate MLCP is via phosphorylation of another protein, CPI-17 (Eto et al, 1997). Phosphorylated CPI-17 then can directly phosphorylate MLCP, thus inactivating MLCP. Thus RhoA and ROK promote smooth bladder contractility by inactivation of MLCP (Fig. 69-15).

BOX 69-1 Detrusor Smooth Muscle Contraction Sequence

- Ca^{2+} binds to calmodulin (CaM), activating it.
- CaM activates the kinase enzyme (myosin light-chain kinase).
- The kinase enzyme catalyzes phosphate transfer from adenosine triphosphate to myosin, allowing myosin to interact with actin of the thin filaments.
- Smooth muscle relaxes with intracellular decrease in Ca^{2+} levels.

RhoA/RhoA kinase (ROK) inactivation of MLCP by phosphorylation

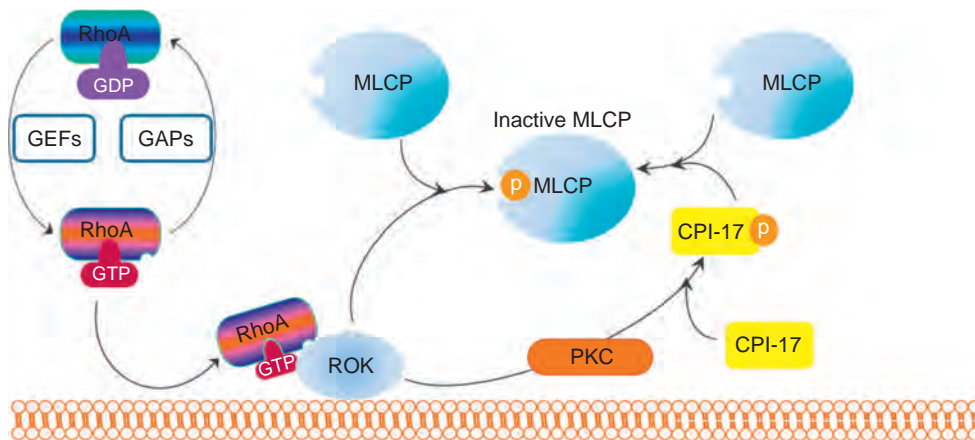

Figure 69-15. Pathways for RhoA and Rho kinase (ROK) interaction with myosin light chain phosphatase (MLCP) in regulating smooth muscle contractility. See text for details. GAPs, GTPase-activating proteins; GDP, guanosine diphosphate; GEFs, guanine nucleotide exchange factors; GTP, guanosine triphosphate; MLCP, myosin light chain phosphatase; PKC, protein kinase C.

Membrane Electrical Properties and Action Potentials

Smooth muscle cellular membrane potential is critical in regulating contraction because smooth muscle cells are excitable (can generate APs) and contractility is dependent on the membrane potential. One must keep in mind that studies of membrane properties of single smooth muscle cells do not take into account that the detrusor functions as a syncytium of cells involving gap junctions that allow electrical coupling among the cells. Furthermore, it is likely that in certain species, detrusor muscle interstitial cells, with their own intrinsic pacemaker activities, modulate smooth muscle cell excitability. Therefore, although single cell smooth muscle studies allow the ability to perform patch-clamp electrophysiologic experiments to study membrane properties, these findings are not necessarily reflective of the behavior of the syncytium of smooth muscle cells.

The membrane potential of a cell, in millivolts (mV), is created primarily by concentration differences between intracellular and extracellular spaces of the ions Na^+ , K^+ , and Cl^- . The approximate concentrations of these ions are as follows:

ION CONCENTRATION (mEq/l)	Na^+	K^+	Cl^-
Intracellular	5-15 (low)	130-140 (high)	4-30 (low)
Extracellular	130-140 (high)	3-5 (low)	105-115 (high)

The equation for calculating membrane potential is determined by the Goldman-Hodgkin-Katz voltage equation, as follows:

$$E_m = \frac{RT}{F} \ln \left(\frac{P_{\text{Na}}[\text{Na}]_o + P_{\text{K}}[\text{K}]_o + P_{\text{Cl}}[\text{Cl}]_i}{P_{\text{Na}}[\text{Na}]_i + P_{\text{K}}[\text{K}]_i + P_{\text{Cl}}[\text{Cl}]_o} \right)$$

where

E_m = membrane potential

R = universal gas constant

T = absolute temperature

F = Faraday constant

P_{Na} , P_{K} , or P_{Cl} = permeability to that ion in arbitrary units

$[\dots]_o$ = concentration of that ion, outside (extracellular)

$[\dots]_i$ = concentration of that ion, inside (intracellular).

At rest, most cells are permeable to K^+ but impermeable to Na^+ and Cl^- (P_{Na} and $P_{\text{Cl}} = 0$); thus the aforementioned equation for resting membrane potential essentially becomes the reversal potential for K^+ , which is -62 mV. However, if the membrane becomes permeable Na^+ and Cl^- , the membrane potential will reflect the contribution of the electrochemical gradient of all these ions. The reversal potentials for Na^+ and Cl^- are approximately $+65$ mV and -85 mV, respectively. The resting membrane potential of human detrusor muscle cells varies and has been measured at -50 to -60 mV (Montgomery and Fry, 1992; Fry et al, 2002), although more recent measurements in cultured human detrusor smooth muscle cells were more depolarized at -28 mV (Hristov et al, 2011).

Guinea pig smooth muscle cell APs were studied in detail by Klöckner (Klöckner and Isenberg, 1985). Pulse current (current passed from inside the cell to outside) via a patch electrode induced an AP, and continuous current resulted in a train of repetitive APs. The morphology of the AP tracings was typical of that of excitable cells, with four phases: phase 0, slow depolarization; phase 1, fast upstroke; phase 2, repolarization; and phase 3, hyperpolarization (Fig. 69-16). With use of voltage clamping techniques and pharmacologic channel blockers or changes in ion concentrations in extracellular buffer, the types of ionic currents that make up the phases of smooth muscle AP tracing were determined (see Fig. 69-16). Phase 1 fast upstroke of the AP is composed of a Ca^{2+} inward current (abbreviated I_{Ca}). Phases 2 repolarization and 3 hyperpolarization of AP are the result of a K^+ outward current (abbreviated I_{K}). These ionic currents are mediated by various ion channels.

The I_{K} that occurs during phases 2 and 3 of the AP is the result of K^+ flowing out of the cell through different K^+ channels including small and large conductance calcium-activated K^+ channels (SK and BK, respectively) and voltage-gated K^+ channels (Kv) (Heppner et al, 1997; Hristov et al, 2011). Blockage or inhibition of any of these K^+ channels would promote myocyte contractility and increase

BLADDER SMOOTH MUSCLE CELL ACTION POTENTIAL AND SIMULTANEOUS CURRENT TRACING

Figure 69-16. The membrane potential (*upper panel*) and the current flow (*lower panel*) in a detrusor myocyte action potential (AP). There are four phases of the action potential, and each phase is mediated by a different ionic current. Phase 0 is slow depolarization. Phase 1 is the fast upstroke of the AP mediated by Ca^{2+} inward current (I_{Ca}). Phases 2 and 3 are hyperpolarization of the AP mediated by K^+ outward current (I_{K}).

the propensity for spontaneous myocyte activity. Of these different types of K^+ channels, BK is the most critical. BK regulates myocyte contractility by regulating the membrane potential, which in turn determines activity of the L-type voltage-dependent calcium channel (VDCC), which in turn determines $(Ca^{2+})_i$ and therefore the contractility of the myocyte.

Excitation-Contraction Coupling

When ACh, released by postganglionic parasympathetic nerve terminals, activates smooth muscle muscarinic M_3 receptors, smooth muscle intracellular Ca^{2+} concentration increases through two mechanisms: extracellular entry through VDCC L-type Ca^{2+} channels (Andersson and Arner, 2004; Andersson and Wein, 2004; Schneider et al, 2004a, 2004b; Nausch et al, 2010) and release of intracellular Ca^{2+} stores via G-protein activation with resultant inositol triphosphate (IP_3) production (Iacovou et al, 1990; Eglen et al, 1994; Harriss et al, 1995; Hashitani et al, 2000; Fry et al, 2002; Braverman et al, 2006a). Because the M_3 receptor is a canonical G_q -coupled protein (seven transmembrane domains), the downstream mechanisms after M_3 activation resulting in release of intracellular Ca^{2+} are reviewed in detail (Fig. 69-17). Other canonical receptors that share the same G_q -activated downstream mechanisms include all the odd muscarinic receptor subtypes (M_1 , M_3 , M_5), α_1 -adrenoreceptors, angiotensin II receptors, histamine H_1 receptors, and 5-HT₂ serotonin receptors, although this is not the complete list (the 2012 Nobel Prize in Chemistry was awarded to Drs. Brian Kobilka and Robert Lefkowitz for their work in unraveling how G-coupled receptors work). Once the M_3 receptor is activated by ACh, it activates the α subunit of the G_q protein. The activated G protein then activates the membrane-bound enzyme, phospholipase C (PLC). Activated PLC cleaves a membrane phospholipid, PIP_2 (phosphatidylinositol 4,5-bisphosphate), to form

cytosolic IP_3 (inositol triphosphate). IP_3 binds to its receptor at the SR, which causes stored Ca^{2+} to be released. The other product of PIP_2 cleavage is diacylglycerol (DAG), which remains membrane bound. DAG binds to protein kinase C (PKC), which is bound to the membrane, thereby activating PKC. PKC is a protein kinase that goes on to phosphorylate myriad proteins to induce secondary signals. Figure 69-17 shows a diagram of the two categories of secondary messenger pathway that all G-coupled receptors follow: One pathway is the IP_3 /PKC pathway, and the other is the cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) pathway. The M_2 receptor subtype is coupled to $G_{i/o}$ and results in increased cAMP and activation of PKA. It has been shown in transgenic animals, where selective deletion of either M_2 or M_3 receptors is created, that M_3 is the subtype that mediates the bladder contractions in the mouse and humans (Matsui et al, 2000; Fetscher et al, 2002; Stengel et al, 2002).

The dogma that the release of intracellular stores of Ca^{2+} is the main driver for nerve-induced smooth muscle contraction has been challenged. Investigators have shown in mouse detrusor smooth muscle that Ca^{2+} entering through L-type VDCCs is the only driver of contraction (Nausch et al, 2010) after nerve stimulation with electric field stimulation (EFS), which causes efferent nerves to release neurotransmitters. EFS-induced smooth muscle contraction was reduced with an anticholinergic (atropine) and VDCC blocker (diltiazem), but EFS-induced contractions were not reduced by blocking IP_3 -mediated signaling or inhibition of PLC. In this study, all purinergic components were blocked by using α,β -methylene ATP in the experiments, so only the muscarinic component was being studied.

Although the normal contraction in the human detrusor smooth muscle is mediated by ACh, in disease states the excitation neurotransmitter could possibly be caused by ATP. Human bladders from obstructed and OAB subjects were studied and found

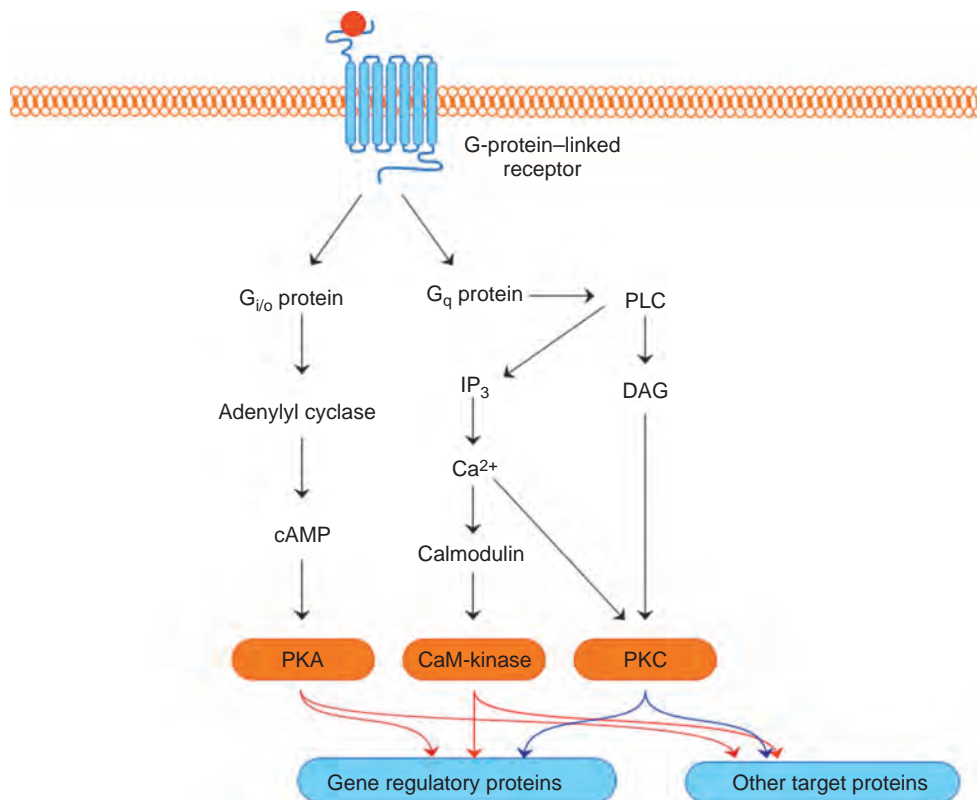

Figure 69-17. Paradigm for G-protein-linked receptor downstream mechanisms. Even muscarinic subtype receptors (M_2 , M_4) are $G_{i/o}$ -protein coupled. Odd muscarinic subtype receptors (M_1 , M_3 , M_5) are G_q protein coupled. CaM, calmodulin; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; IP_3 , inositol triphosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C.

to have atropine-resistant contractions that were blocked by the ATP-receptor blocker α,β -methylene ATP, suggesting a purinergic excitatory component to the pathologic bladder contractions (Bayliss et al, 1999). In this study, normal human bladders had no purinergic excitation-coupling signaling. More recent investigations in mouse smooth bladder revealed that both P2X₁ and M₃ receptors contribute to the muscle contractions, but it is interesting to note that there appeared to be an element of suppression of the muscarinic excitation-contraction coupling by the purinergic activation (Heppner et al, 2009). These investigators used their experimental findings to propose a hypothesis of how both DO (LUTS) and underactivity can occur simultaneously in a patient, as with detrusor hyperactivity with impaired contractility (DHIC) (Resnick and Yalla, 1987). It has already been shown that purinergic signaling is increased in the human aging bladder (Yoshida et al, 2001). And if the interplay between purinergic and muscarinic signaling occurs in human as it does in mice, then this increased purinergic signaling detected in elderly human bladders can explain the occurrence of LUTS and overactivity (through increased purinergic-activated afferent activity; see later) with simultaneous incomplete bladder emptying (detrusor underactivity or impaired contractility through suppression of muscarinic signaling). This describes DHIC. Furthermore, this interplay gives rise to the possibility of treating DHIC by blocking purinergic signaling.

Calcium Signaling in Detrusor Myocyte

Because contractility of the smooth muscle is dependent on Ca^{2+} , there are many control mechanisms regulating intracellular Ca^{2+} . I_{Ca} (Ca^{2+} inward current) occurring during the phase 1 fast upstroke of APs is mediated by voltage-dependent Ca^{2+} channels (gene name is *CaV* or *CACNA1*). As discussed in the previous section, Ca^{2+} entry through the VDCC is likely the main contributor to the contraction. There are several types of VDCCs, but the two types that are important in bladder smooth muscle contraction are L-type (L = long lasting) and T-type (T = transient). The classic VDCC, the L-type, which is blocked by traditional Ca^{2+} blockers such as nifedipine (a dihydropyridine), diltiazem (a nondihydropyridine), and verapamil (a phenylalkylamine), is present on smooth muscle cells and is activated by AP-induced depolarization (Rivera and Brading, 2006; Nausch et al, 2010). T-type VDCCs responded to lower magnitudes of depolarization, had smaller conductance, and have no highly specific blockers yet (Fry and Jabr, 2014). The participation of T-type VDCCs in bladder smooth muscle physiology may allow a finer control of the excitation coupling and/or be important in detrusor contractile pathologies. Calcium imaging is a technique whereby one can visualize changes in single-cell intracellular Ca^{2+} concentrations ($[\text{Ca}^{2+}]_i$) by using calcium dyes that fluoresce with intensities directly correlated with $(\text{Ca}^{2+})_i$. Calcium imaging during the course of a smooth muscle cell contraction reveals a “calcium flash” caused by a sudden large increase in $(\text{Ca}^{2+})_i$ followed by mechanical contraction with shortening of the cell. This influx of Ca^{2+} through both types of VDCC initiates the actinomyosin cross-bridge cycling as detailed in the previous section.

When $(\text{Ca}^{2+})_i$ rises via entry through VDCCs during the AP, this causes the SR to release its stores of Ca^{2+} (internal stores) through ryanodine receptors (RyRs)—a phenomenon called *calcium-induced calcium release* (CICR). Internal stores of Ca^{2+} released are visualized as “calcium sparks” (from microfluorometry) that were first discovered in arterial smooth muscle (Nelson et al, 1995). These calcium sparks activate (open) the nearby membrane-associated calcium-activated large conductance potassium channel (BK or gene name *KCNMA1*), which lets potassium out of the cell, thus hyperpolarizing the cell and relaxing the smooth muscle cell (see next paragraph about I_K portion of the AP). These calcium sparks are the cause of the spontaneous transient outward currents (STOCs) of K^+ mediated by the BK channel. Calcium sparks were studied in detrusor smooth muscle (Collier et al, 2000; Herrera et al, 2001). In bladder myocytes, the calcium sparks (e.g., RyR openings) were not tightly linked to the gating of L-type VDCCs, as in cardiac myocytes, because the SR is not as physically close to the VDCC in the bladder

myocytes as in the cardiac myocytes. Similar to arterial myocytes, the calcium sparks in detrusor myocytes also activate BK channels. These interactions are shown in the animation on the Expert Consult website.

Intracellular Ca^{2+} also activates a variety of cellular responses when it enters the cytoplasm of a cell. To be effective as a signal, its concentration must be returned to submicromolar levels, driven by ATP pumps. The Ca^{2+} pump is a membrane-bound, Ca^{2+} -activated ATPase, similar to the Na^+ - K^+ pump that controls ion balance and membrane potential in all animal cells. These pumps belong to a superfamily of ATPases known as *P type*, because they depend on the autophosphorylation of a conserved aspartic acid residue using ATP. The rise in intracellular Ca^{2+} can be lowered by pumping Ca^{2+} back into the SR or mitochondria or out into the extracellular space (Fig. 69-18).

When intracellular stores of Ca^{2+} within the SR are depleted, the myocyte has a mechanism by which another type of Ca^{2+} channel (ORAI) opens, thus allowing influx of extracellular Ca^{2+} to refill the SR stores. This process is called the *store-operated Ca^{2+} entry* (SOCE) or capacitive Ca^{2+} entry. The sensor for SR Ca^{2+} concentration is the protein called STIM (stromal interaction molecule) (Roos et al, 2005). When STIM senses low Ca^{2+} concentrations, STIM proteins aggregate to form discrete membrane clusters that tether the plasma membrane protein ORAI, allowing tetramers of ORAI to form a pore for extracellular Ca^{2+} entry into the cell (Penna et al, 2008). This Ca^{2+} channel composed of multiunits of ORAI is called CRAC (calcium release-activated channel). The electrophysiologic current measured from Ca^{2+} entry through CRAC is denoted I_{CRAC} . Although SOCE has been shown to be present in various other smooth muscles, SOCE has not been measured yet in detrusor myocytes but is likely to exist.

Propagation of Electrical Responses

Specialized proteins called **connexin 43 (gap-junction proteins)** are expressed between the membranes of connected smooth muscle cells. The basic unit (monomer) of Cx43 is composed of four transmembrane domains with the carboxy-terminal and amino-terminal intracellular (Fig. 69-19). Six monomers of Cx43 are arranged as a hexamer unit with a central pore channel. The hexameric unit Cx43 of two neighboring myocytes will have to dock to align the central pore so that ions can flow from one myocyte to another. The electrically coupled myocytes can be measured using double whole-cell patch (DWCP) electrophysiology. This technique was performed on cultured human myocytes and gap junction currents were detected; also, Western blots confirmed the presence of Cx43 (Wang et al, 2006).

However, lack of fused tetanic contractions in normal detrusor smooth muscle strips suggests that there is poor electrical coupling between smooth muscle cells (Uvelius and Mattiasson, 1986). Measurements of tissue impedance support the observation that the detrusor is less well coupled electrically than other smooth muscles (Brading and Mostwin, 1989; Parekh et al, 1990). Poor coupling could be a feature of a normal detrusor that prevents synchronous activation of the smooth muscle cells during bladder filling. Nevertheless, some degree of coupling within a muscle bundle clearly does exist, because it is possible to measure the length constant of a bundle (Seki et al, 1992). There is also evidence for gap-junction coupling between detrusor cells in humans and guinea pigs, detected by whole-cell patch clamp recordings (Wang et al, 2006) and Ca^{2+} imaging (Neuhaus et al, 2002), respectively. Significant expression of Cx43 and Cx45 gap-junction proteins is found in human detrusor muscles (John et al, 2003; Wang et al, 2006). However, electrical couplings between detrusor cells seem to be reduced during postnatal development because coordinated, large-amplitude, low-frequency contractile activity as seen in the neonate rat bladder declines and is replaced by low-amplitude, high-frequency, more irregular activity in older rats, which appears to depend on the disruption of the intercellular smooth muscle communication (Szell et al, 2003). It has also been suggested that a change in the properties of the cell coupling may

MECHANISMS OF MAINTAINING CALCIUM LEVEL IN THE MYOCYTE

Figure 69-18. Intracellular calcium (green circles) in the detrusor myocyte can be regulated by various mechanisms: (1) exchanging for Na⁺ ion; (2) pumping out of cell using adenosine triphosphate (ATP); (3) pumping into sarcoplasmic reticulum (SR) with SERCA/ATP; (4) binding to calcium-binding molecule; (5) pumping into mitochondria. ADP, adenosine diphosphate.

MOLECULAR STRUCTURE AND FUNCTION OF THE GAP JUNCTIONS

Connexin has four transmembrane domains

Six connexin molecules form the channel of the connexin

B, Six connexin units (monomers) form a hemichannel with a central pore. C, Two hemichannels dock together to form a channel that allows passage of ions between cells. D, Patch clamp can reveal electrically coupled cells.

underlie the generation of the uninhibited detrusor contractions occurring in overactive and aging bladders (Seki et al, 1992; Brading, 1997b, 2006).

Detrusor Interstitial Cells

Recent evidence suggests that the “normal” bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of DO. In a rat model for DO, local areas of spontaneous contractions are increased and more coordinated in rat bladders with partial outlet obstruction (Drake et al, 2003). However, it is still not clear which cells generate spontaneous activity in the bladder. As mentioned before, detrusor myocytes could be spontaneously active, and electrical coupling through gap junctions could trigger spontaneous contractions (Brading, 1997b, 2006). Alternatively, another population of cells in the bladder known as *interstitial cells* or *myofibroblasts* has been proposed for a pacemaking role in spontaneous activity of the bladder (Andersson and Arner, 2004; Kumar et al, 2005). Interstitial cells have been identified in the human and guinea pig ureter, urethra, and bladder body (Kumar et al, 2005; Hashitani, 2006; Fry et al, 2007).

Interstitial cells, in addition to being located in the suburothelial layer, are also found in the detrusor layer and have been shown to be spontaneously active (Kumar et al, 2005). These cells are stained for c-KIT and located along both boundaries of muscle bundles in the guinea pig bladder (McCloskey and Gurney, 2002; Hashitani et al, 2004; Hashitani, 2006). These cells can fire Ca^{2+} waves in response to cholinergic stimulation by M_3 muscarinic receptor activation and can be spontaneously active, suggesting that they could act as pacemakers or intermediaries in transmission of nerve signals to smooth muscle cells (McCloskey and Gurney, 2002; Johnston et al, 2008) (Fig. 69-20). However, Hashitani and colleagues (2004) have also suggested that interstitial cells in the detrusor may be more important for modulating the transmission of Ca^{2+} transients originating from smooth muscle cells than for being the pacemaker of spontaneous activity because spontaneous Ca^{2+} transients occur independently in smooth muscles and interstitial cells. It has also been demonstrated that the c-KIT tyrosine kinase inhibitor imatinib (Glivec) decreased the amplitude of spontaneous contractions in the guinea pig bladder (Kubota et al, 2004, 2006) and in muscle

strips from the overactive human bladder, in which c-KIT-positive cells were increased compared with normal subjects (Biers et al, 2006), suggesting that targeting these receptors expressed in intradetrusor interstitial cells may provide a new approach for treating OAB. In addition, after application of SNP (an NO donor), interstitial cells throughout the bladder, but not detrusor muscle cells, demonstrate cGMP immunoreactivity (Smet et al, 1996; Gillespie et al, 2004). Thus, increased levels of cGMP found in interstitial cells by using phosphodiesterase-5 (PDE5) inhibitors, for example, may diminish synchronicity between detrusor muscle bundles (Hashitani, 2006). These cells are also a source of PGE_2 because of their expression of cyclooxygenase and a reduction in spontaneous activity of bladder muscle strips by use of PGE_2 receptor (EP) antagonists in rabbits (Collins et al, 2009).

Investigators have found a new class of intradetrusor cells with pacemaker-like properties (Koh et al, 2012; Lee et al, 2014). These cells were not c-KIT positive, but rather expressed platelet-derived growth factor receptor (PDGFR)- α . The reason these investigators searched for this type of cell in the bladder was because the PDGFR- α -positive cells in the gastrointestinal tract have been found to inhibit neurotransmission in the myenteric neural plexus (Cobine et al, 2011; Kurahashi et al, 2011). Although purines, such as ATP, induce initial contraction of the bladder muscle (see the section on **excitation-contraction coupling**), there is also a prolonged relaxation that could be related to the suppression of the muscarinic excitation-coupling (Heppner et al, 2009). However, investigators found that the detrusor PDGFR- α cells, through P_2Y_1 signaling, were the reason for the prolonged relaxation induced by purines (Lee et al, 2014). These investigators theorized that a “dual receptive field”—an excitatory field via P_2X_1 on the smooth muscle and one inhibitory field via P_2Y_1 on the PDGFR- α cells—provides finer regulation of detrusor contractility.

Further research is required to fully understand the role of suburothelial and intradetrusor interstitial cells and their contribution to spontaneous contractions or DO.

KEY POINTS: SMOOTH MUSCLE MECHANICS

- Muscarinic receptors induce detrusor contraction, in response to ACh released from parasympathetic nerve terminals, by calcium entry through Ca^{2+} channels
- Although calcium serves the same triggering role in all muscle types, the mechanism of activation is different in smooth muscle. The contractile response is slower and longer lasting than that of skeletal and cardiac muscle.
- Recent evidence suggests that the “normal” bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of an OAB. A population of cells within the detrusor layer, known as *interstitial cells* or *myofibroblasts*, has been proposed to have a pacemaking role in spontaneous activity of the bladder.

Figure 69-20. Schematic representation of interstitial cells in the detrusor muscle layers. These cells are not contractile but may be pacemakers with spontaneous activity and propagate signals between detrusor muscles. They also express KIT receptors and muscarinic M_3 receptors, and can produce prostaglandins (PG), such as PGE_2 , through activation of cyclooxygenase (COX).

BLADDER MECHANICS

Urinary Storage (Filling)

During urine filling of the bladder, the viscoelastic behavior of the bladder depends on both neuromuscular and mechanical properties. Mechanical properties are extremely sensitive to tissue structure and composition of the bladder wall. In addition to smooth muscle, the human bladder is composed of roughly 50% collagen and 2% elastin. With injury, obstruction, or denervation, collagen content increases (Macarak and Howard, 1999). When contractile protein content exceeds collagen, greater distensibility is achieved (compliance). Conversely, when collagen levels increase, compliance falls. The changes in the thickness of the lamina propria and the detrusor are mechanical requirements for the bladder to accommodate increasing urine volume. During filling, the lamina propria thins at a faster rate than the muscle wall. It has been proposed that bladder wall thinning during filling is the result

of a rearrangement of the muscle bundles and also alteration of collagen coil structure (Macarak and Howard, 1999). A combination of muscle and connective tissue spatial changes is required to accommodate urine at low intravesical pressures (Chang et al, 1999). During filling, the detrusor reorganizes and muscle bundles shift position from a top-to-bottom to a side-to-side configuration. During reorganization, the coiled type III collagen fibers connecting the muscle bundles orthogonally become extended, longer, and taut and assume an orientation such that the fibers become oriented parallel to the lumen.

Bladder compliance (C) is defined as the change in volume (V) relative to the corresponding change in intravesical pressure (P):

$$C = \Delta V / \Delta P$$

Filling the bladder at a slow physiologic rate maintains an intravesical pressure of less than 10 cm H₂O (Klevmark, 1974). However, the compliance of the bladder is dependent on the rate at which fluid is instilled into the bladder (Coolsaet, 1985). This phenomenon can be seen in urodynamics when the intravesical pressure can drop when filling is slowed or stopped. The pressure-volume curve during filling of the bladder is dependent on several factors including (1) collagen, elastin, and smooth muscle as passive structures; (2) active properties of the smooth muscle; and (3) geometry of the bladder. Therefore, when there is decreased compliance of the bladder (steep filling curve), it may be the result of multiple factors including (1) fast filling rate; (2) change in composition of the bladder wall (e.g., more collagen, less elastin); (3) hyperactivity of the smooth muscle; and (4) a combination of any of these factors. The compliance of a typical bladder in 559 women with stress incontinence was measured with standardized urodynamics (50 mL/min filling rate). The data showed that the mean maximum cystometric capacity (MCC) was 392 mL; intravesical pressure (Pdet) rose from 2 cm H₂O at the beginning of fill to 6 cm H₂O at MCC (Nager et al, 2007).

Acute spinal transection of the bladder did not alter bladder compliance, although pelvic nerve transection did decrease compliance (Langley and Whiteside, 1951). However, recent animal studies have suggested that central neural input is required for bladder compliance and that this is an active afferent neural process (Smith et al, 2012b). These investigators theorized that afferent signals arising from the bladder wall during filling of the bladder are relayed to the CNS, which in turn inhibits spontaneous smooth muscle contractility, thus maintaining high bladder compliance during filling. In other words, the nervous system, in addition to viscoelastic properties of the bladder wall, has a role in maintaining bladder compliance during filling.

The bladder muscle has a broad length-tension relationship, allowing tension to be developed over a large range of resting muscle lengths (Uvelius and Gabella, 1980). The tissue shows viscoelasticity that influences muscle tension and manifests as total bladder wall tension (Venegas, 1991). Isolated detrusor strips show spontaneous mechanical activity to a variable extent. It is more frequently seen in bladders from small mammals (Sibley, 1984) but can also be seen in muscle strips from human detrusor. However, spontaneous fused tetanic contractions, such as those commonly seen in smooth muscles from the gastrointestinal tract and uterus, are almost never seen in normal bladders.

Voiding Mechanics

Intravesical pressure reflects the combined factors of abdominal (Pabd) and detrusor (Pdet) pressures. Therefore,

$$P_{det} = P_{ves} - P_{abd}$$

Micturition relies on a neurally mediated detrusor contraction, causing Pdet to rise without a significant change in Pabd. To assess the strength of a detrusor contraction, Pdet alone is an insufficient measure. A muscle can use energy either to generate force or to shorten its length. Because the bladder is a hollow viscus, the force

developed contributes to Pdet, whereas the velocity of shortening relates to urine flow (Q). There is a trade-off between generating Pdet and urine flow. This has been nicely reviewed by Griffiths (1988). If urethral resistance is low, as in women with sphincter insufficiency and even in normal continent women, Pdet may be almost undetectable; yet, these women with modest Pdet would have normal flow rates. In a population of 384 stress-incontinent women, the mean Pdet at Qmax on pressure-flow urodynamics study was 19 cm H₂O (Nager et al, 2007). In a group of 30 healthy men who underwent ambulatory urodynamics, Pdet at Qmax ranged from 60 to 70 cm H₂O (Schmidt et al, 2004). The trade-off between Pdet and Q resembles a curve for constant mechanical power (W) in which

$$W = P_{det} \times Q$$

The equation explains why a woman could have normal detrusor contractility and normal detrusor power despite low voiding pressure. During micturition, Pdet reflects outlet resistance. When the urethra opens widely with a high flow (Q), little Pdet is needed to achieve the work necessary to empty the bladder. The key message is that low voiding pressure in a woman does not equate with impaired detrusor contractility; she may simply be able to open her urethra widely. Moreover, pressure-flow nomograms developed for men for diagnosis of obstruction should not be applied to women without validation.

Motor Sensory Network in Detrusor Muscle

Based on anatomic immunohistochemical localization studies of nerve fibers in the guinea pig, Gillespie has proposed a "motor sensory" network within the detrusor muscle wall (Gillespie et al, 2006) (Fig. 69-21). This network involves the presence of sensory fibers (green and red lines in Fig. 69-21) next to detrusor myocytes and intradetrusor interstitial cells. Because the detrusor has spontaneous activity (as micromotions and/or nonvoiding contractions), the spontaneous smooth muscle contractions trigger sensory signals to the host. An increase in spontaneous activity of the detrusor smooth muscle could be interpreted as an urgency episode. Certainly, this model could help explain how decreasing smooth muscle spontaneous activity (e.g., with antimuscarinics) could decrease sensory input. The effect of tolterodine (antimuscarinic) and mirabegron (β_3 agonist) in decreasing nonvoiding contractions in a partial urethral obstruction animal model has been shown (Gillespie et al, 2012). However, the investigators did not measure the pelvic afferent output to determine whether that was reduced with the reduction of the nonvoiding contractions. Bladder wall micromotions were measured in women with sensory urgency, though the sample size was small (N = 6) (Drake et al, 2005). This motor sensory network ties in the concept that it is not easy to separate the function of the bladder organ into simple efferent and afferent activities, because these two events are inexorably linked.

NEURAL CONTROL OF THE LOWER URINARY TRACT

Peripheral Nervous System

The LUT is innervated by three sets of peripheral nerves involving the parasympathetic, sympathetic, and somatic nervous systems (Fig. 69-22). Pelvic parasympathetic nerves arise at the sacral level of the spinal cord, excite the bladder, and relax the urethra. Lumbar sympathetic nerves inhibit the bladder body and excite the bladder base and urethra. Pudendal nerves excite the EUS. These nerves contain afferent (sensory) as well as efferent axons (Wein, 1992; de Groat et al, 1993; Sugaya et al, 1997; Yoshimura et al, 2008).

Parasympathetic Pathways

Parasympathetic preganglionic neurons innervating the LUT are located in the lateral part of the sacral intermediate gray matter in

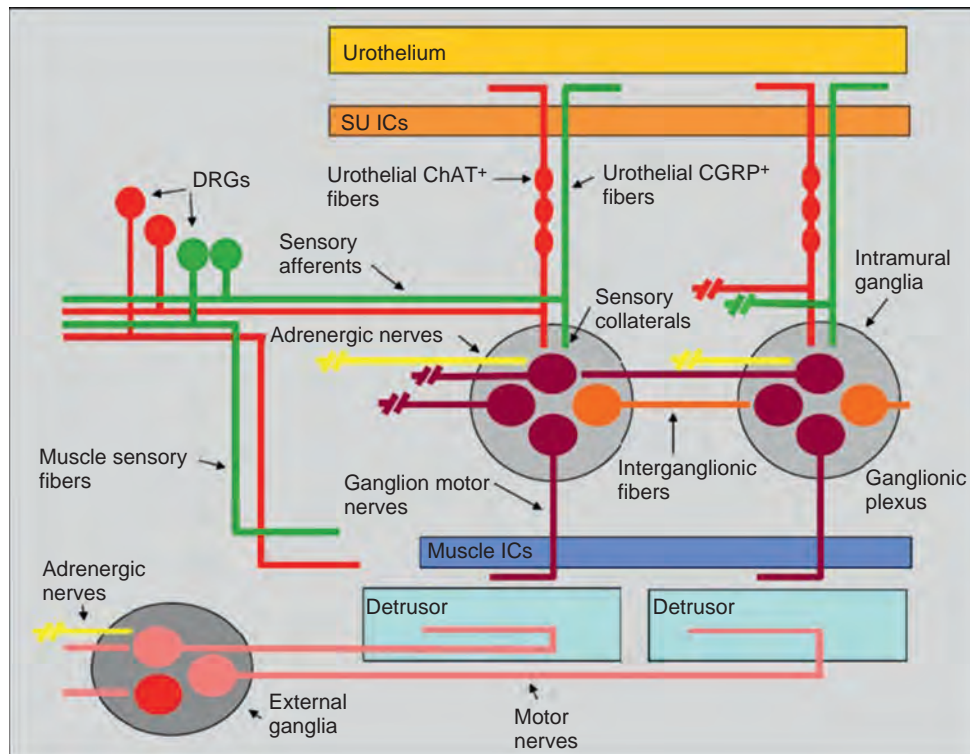

Figure 69-21. Motor sensory network within the detrusor muscle wall. Sensory afferents surround detrusor myocytes. Gray circles represent (1) intradetrusor ganglia that supply postganglionic efferents to detrusor muscle and (2) external ganglia. Detrusor myocyte spontaneous activity can trigger sensory afferents. CGRP, calcitonin gene-related peptide; ChAT, choline acetyltransferase; DRGs, dorsal root ganglia; ICs, interstitial cells; SU, suburothelial.

a region termed the *sacral parasympathetic nucleus* (Nadelhaft et al, 1980; Morgan et al, 1981; de Groat et al, 1993; Morgan et al, 1993; de Groat et al, 1996). Parasympathetic preganglionic neurons send axons through the ventral roots to peripheral ganglia, where they release the excitatory transmitter ACh (de Groat and Booth, 1993). Parasympathetic postganglionic neurons in humans are located in the detrusor wall layer as well as in the pelvic plexus. This is an important fact to remember because patients with cauda equina or pelvic plexus injury are neurologically decentralized but may not be completely denervated. Cauda equina injury allows possible afferent and efferent neuron interconnection at the level of the intramural ganglia (de Groat et al, 1993, 1996).

Sympathetic Pathways

Sympathetic outflow from the rostral lumbar spinal cord provides a noradrenergic excitatory and inhibitory input to the bladder and urethra (Andersson, 1993). Activation of sympathetic nerves induces relaxation of the bladder body and contraction of the bladder outlet and urethra, which contribute to urine storage in the bladder. The peripheral sympathetic pathways follow a complex route that passes through the sympathetic chain ganglia to the inferior mesenteric ganglia and then through the hypogastric nerves to the pelvic ganglia.

Somatic Pathways

The EUS motoneurons are located along the lateral border of the ventral horn, commonly referred to as the *Onuf nucleus* (Fig. 69-23) (Thor et al, 1989). Sphincter motoneurons also exhibit transversely oriented dendritic bundles that project laterally into the lateral funiculus, dorsally into the intermediate gray matter, and dorsomedially toward the central canal.

Afferent Pathways

Overview: Properties of Afferent Neurons. The bladder and LUT serve to store and evacuate urine and are controlled by a complex interaction of neural mechanisms organized by local, spinal, and brain circuits. The majority of time is spent in storage mode, during which the bladder accommodates urine and maintains continence via reflexes that prevent contraction of bladder smooth muscle and promote contraction of the urethral sphincter. This switches during micturition when the bladder contracts and the sphincter relaxes to facilitate voiding. This switch relies on sensory signals, which provide the input to the reflex circuits that control bladder filling and emptying and are also the source of both nonpainful sensations of fullness and pain. Dysfunction leads to a number of disorders such as OAB syndrome and BPS/IC, with symptoms including urgency, pain, and urinary incontinence. Currently available therapeutic approaches are aimed primarily at reducing bladder contraction to relieve intravesical pressure and maintain continence. More recently, interest in bladder afferent signaling has been driven by the realization that symptoms are a feature of dysregulated storage sensations rather than exaggerated contractile responses and therefore targeting afferent mechanisms may be a rational approach to treatment.

Pathways to the Spinal Cord. Afferent fibers innervate the LUT via pelvic, hypogastric (lumbar splanchnic), and pudendal nerves. These nerves are mixed nerves that also contain the efferent parasympathetic, sympathetic, and motor fibers supplying the bladder, urethra, and sphincters. Axonally transported dyes taken up by afferent nerves are transported to the afferent cell bodies in the lumbosacral dorsal root ganglia (DRG) and the afferent terminations in the dorsal horn of the spinal cord. The primary afferent neurons of the pelvic and pudendal nerves are contained in sacral DRG, whereas afferent innervation in the hypogastric

Figure 69-22. Diagram showing the sympathetic, parasympathetic, and somatic innervation of the urogenital tract of the male cat. Sympathetic preganglionic pathways emerge from the lumbar spinal cord and pass to the sympathetic chain ganglia (SCG) and then through the inferior splanchnic nerves (ISN) to the inferior mesenteric ganglia (IMG). Preganglionic and postganglionic sympathetic axons then travel in the hypogastric nerve (HGN) to the pelvic plexus and the urogenital organs. Parasympathetic preganglionic axons that originate in the sacral spinal cord pass in the pelvic nerve to ganglion cells in the pelvic plexus and to distal ganglia in the organs. Sacral somatic pathways are contained in the pudendal nerve, which provides an innervation to the penis and the ischiocavernosus (IC), bulbocavernosus (BC), and external urethral sphincter (EUS) muscles. The pudendal and pelvic nerves also receive postganglionic axons from the caudal sympathetic chain ganglia. These three sets of nerves contain afferent axons from the lumbosacral dorsal root ganglia. PG, prostate gland; U, ureter; VD, vas deferens.

nerves arises in the rostral lumbar DRG. The central axons of the DRG neurons carry the sensory information from the LUT to second-order neurons in the spinal cord (Morgan et al, 1981; de Groat, 1986; Thor et al, 1989; de Groat et al, 1996). These second-order neurons provide the basis for spinal reflexes and ascending pathways to higher brain regions involved in micturition, continence, and mediation of sensation.

Pelvic nerve afferents, which monitor the volume of the bladder and the amplitude of the bladder contraction, consist of myelinated (Aδ) and unmyelinated (C) axons (Table 69-2, Fig. 69-24). During neuropathic conditions (spinal cord injury) and possibly inflammatory conditions, there is recruitment of C fibers that form a new functional afferent pathway that can cause urgency incontinence and possibly bladder pain (Fig. 69-25).

There is great interest in understanding the nature and origins of bladder sensation. "Sensing" bladder volume is of particular relevance during bladder storage. Nathan (1956) described the sensations of awareness and desire to micturate involving bladder distention (stretch) and contraction and suggested that these could be mapped to the urinary bladder. In contrast, the sensation of imminent micturition may originate not in the urinary bladder, but rather from the urethra. More recent ideas link bladder filling with

episodic bursts of sensation (correlating with afferent discharge) that increase in intensity during filling, with the final episodes being the most intense and often described as "urgency" (Chapple and Wein, 2005). Afferent discharges that occur during a bladder contraction have an important reflex function and appear to reinforce the central drive that maintains the detrusor contraction. Afferent nerves that respond to both distention and contraction—that is, "in-series tension receptors"—have been identified in the pelvic and hypogastric nerves of cats and rats (Iggo, 1955; Floyd et al, 1976; Morrison, 1997). Afferents that respond only to bladder distention have been identified in the rat bladder (Morrison et al, 1998) and appear to be volume receptors, possibly sensitive to stretch of the urothelium. In the cat bladder, the presence of in-series tension receptors has also been reported (Downie and Armour, 1992). In the rat, there is evidence that many C bladder afferents are stretch receptors that do not respond to bladder contractions, a property that distinguishes them from in-series tension receptors (Morrison et al, 1998).

Functional Properties of Bladder Afferents. In the human bladder, ultrastructural studies have identified only unmyelinated nerves in the urothelium and immediate suburothelial layer, with small myelinated nerves being closely associated with the smooth

Figure 69-23. Cross section of sacral spinal cord; neuroanatomic distribution of primary afferent and efferent components of storage and micturition reflexes. For purposes of clarity, afferent components are shown only on the *left*, and efferent components are shown only on the *right*. Both components are, of course, distributed bilaterally and thus overlap extensively. Visceral afferent components represent bladder, urethral, and genital (glans penis or clitoris) afferent fibers contained in the pelvic and pudendal nerves. Cutaneous perineal afferent components represent afferent fibers that innervate the perineal skin contained in the pudendal nerve. Muscle spindle afferent components represent Ia/b afferent fibers contained in the levator ani nerve that innervate muscle spindles in the levator ani muscle. EUS, external urethral sphincter; LCP, lateral collateral projection; MCP, medial collateral projection; SPN, sacral parasympathetic nucleus.

TABLE 69-2 Bladder Afferent Properties

FIBER TYPE	LOCATION	NORMAL FUNCTION	INFLAMMATION EFFECT
Aδ (finely myelinated axons)	Smooth muscle	Sense bladder fullness (wall tension)	Increase discharge at lower pressure threshold
C fiber (unmyelinated axons)	Mucosa	Respond to stretch (bladder volume sensors)	Increase discharge at lower threshold
C fiber (unmyelinated axons)	Mucosa muscle	Nociception to overdistention Silent afferent	Sensitive to irritants Become mechanosensitive and unmask new afferent pathway during inflammation

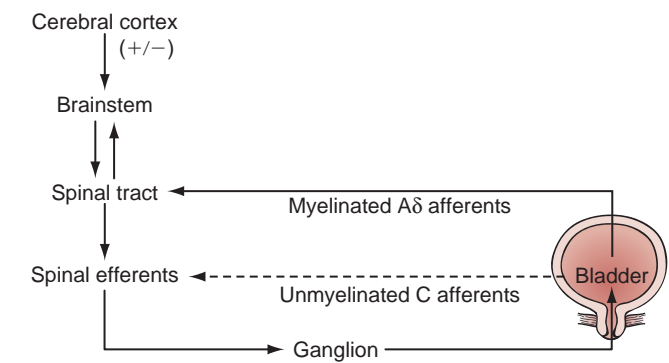

Figure 69-24. Illustration depicting the predominant Aδ afferent contribution to the normal micturition reflex. C-fibers (*dotted line*) are normally silent unless turned on by pathology.

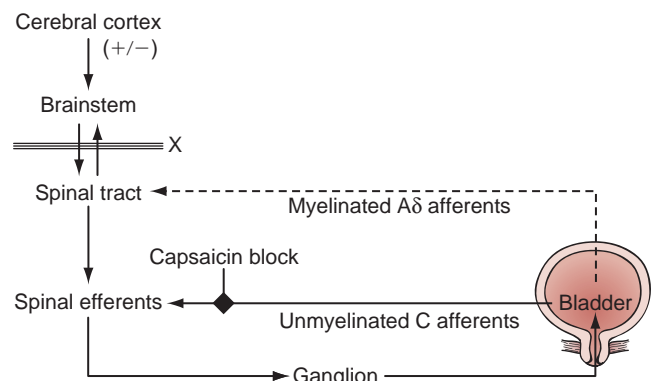

Figure 69-25. Illustration depicting the switch in afferent contribution to the micturition reflex from Aδ-fiber predominant to C-fiber predominant with neurologic diseases, aging, and possibly inflammatory disease. Note that capsaicin (and other vanilloids) can block the C-fiber contribution under these conditions.

muscle layers (Wiseman et al, 2002). The plexus of afferent nerves in the lamina propria is thickest in bladder neck and in the initial portion of the urethra, and becomes progressively less dense in adjacent regions such that the cranial region of the bladder has no afferent axons. In contrast, the afferent innervation of the musculature is more uniform throughout the bladder.

Recording from bladder afferents has revealed the diversity of afferent populations described earlier based on morphology, receptive field site, mechanical and chemical sensitivity, and electrophysiological characteristics. **Conduction velocity measurements confirm the predominance of fibers conducting APs in the A δ and C-fiber range.** The majority of these fibers are mechanosensitive, responding with a range of thresholds from volumes that would be encountered under normal bladder filling to extreme levels of distention that would be considered noxious and give rise to pain. Those with lower activation thresholds have small myelinated axons, whereas unmyelinated fibers in general have higher thresholds for activation. In addition, other afferents do not respond to bladder filling but can be activated by intraluminal chemicals such as hypertonic saline, capsaicin, or ATP, suggesting they may function as chemoreceptors. Still other subpopulations may be so-called silent afferents that have been described elsewhere, including the gastrointestinal tract. These afferents can be sensitized during inflammation, suggesting a role in signaling pain.

In the mouse pelvic nerve, four classes of bladder afferents (serosal, muscular, muscular/urothelial, and urothelial) have been identified based on responses to receptive field stimulation with different mechanical stimuli, including probing, stretch, and stroking the urothelium. Both low-threshold, representing 65% to 80% of the total population, and high-threshold stretch-sensitive muscular afferents are present (Daly et al, 2007; Xu and Gebhart, 2008). The muscular afferents can be sensitized by application of a combination of inflammatory mediators (bradykinin, serotonin, prostaglandin, and histamine at pH 6.0) (Xu and Gebhart, 2008).

A series of studies have used open-sheet preparations of guinea pig bladder to examine the diversity of bladder afferents and to attempt to correlate structure with function. Low-threshold

afferents have terminals in the muscle, described as “antenna-like” endings, and are referred to as *stretch-sensitive muscular mechanoreceptors* (Zagorodnyuk et al, 2006, 2007). These afferents, termed *tension receptors*, also respond to contraction of the detrusor muscle as well as tension generated by elongation during stretch and shortening during contraction. High-threshold afferents are also likely to terminate in the deeper muscle layers or in the serosa. These mechanosensitive endings have receptive fields (located by mechanical probing) associated with blood vessels. Thus, high-threshold afferents respond to high levels of bladder stretch but may also become sensitized in response to inflammation.

Species differences, as well as differences in nomenclature, might account for some of the variations in reported properties of bladder afferents. For example, the conduction velocity that differentiates A δ and C fibers is 2 m/sec in the cat, whereas it is 1.3 m/sec in the rat (Waddell et al, 1989). In the cat, bladder A δ afferents appear to be low-threshold mechanoreceptors (Häbler et al, 1993), whereas bladder C afferents (Häbler et al, 1990) are, in general, mechanosensitive (“silent C fibers”) (see Table 69-2). Some of the latter may be nociceptive and found to be sensitized by intravesical administration of chemicals (such as high potassium), low pH, high osmolality, and irritants such as capsaicin (Maggi et al, 1987; McMahon and Abel, 1987; Wen et al, 1994; Zagorodnyuk et al, 2009) (Fig. 69-26). After exposure to these substances, the sensitivity of bladder mechanoreceptors to distention increases, and some silent afferents become mechanoreceptive.

The bladder neck and proximal urethra contain the largest density of bladder nerves (Yokokawa et al, 1985; Gabella and Davis, 1998). In the urethra, afferent nerves have been reported between the muscle fibers, surrounding blood vessels, within the urothelium, and in a dense suburothelial plexus (Crowe et al, 1986; Tainio, 1993; Fahrenkrug and Hannibal, 1998). The striated sphincter muscle surrounding the urethra receives a very sparse afferent innervation that is localized primarily to nerve bundles passing between the muscle bundles. Specialized tension receptors (muscle spindles) that are innervated by large-diameter myelinated group IA afferents and that are prominent in most striated muscles are

Figure 69-26. Actions of chemical mediators that may sensitize mechanosensory nerve endings in the bladder mucosa. Adenosine triphosphate (ATP) can be released from the urothelium and may sensitize the mechanoreceptors, which respond to stretch of the mucosa during bladder distention. Neuropeptides transported to the sensory ending by axoplasmic transport may be released during distention and chemical stimulation, and neurokinin A can act on NK₂ autoreceptors, which sensitize the mechanosensitive endings. This mechanism can be induced by high urinary potassium concentrations and possibly by other sensitizing solutions within the bladder lumen, such as those with high osmolality or low pH; the presence in the tissues of inflammatory mediators may also sensitize the endings. The smooth muscle can generate force that may influence some mucosal endings, and the production of nerve growth factor is another mechanism that can influence the mechanosensitivity of the sensory ending through the tyrosine kinase (TrkA) receptor.

absent (Gosling et al, 1981) or are present in low density (Lassmann, 1984) in striated sphincter muscles.

Afferent nerves may extend in some species to the luminal surface of the urothelium. In contrast, the urethral epithelium is likely to be part of a signaling system involving projections of neuroendocrine cells, interstitial cells, and sensory nerve endings. There is speculation that these urethral-neuroendocrine cells (often termed *paraneurons*) (Hashimoto et al, 1999) could release mediators such as neuropeptides or serotonin, which via activation of adjacent sensory nerves can stimulate urethral reflexes. Such types of cells are not unlike those in other types of epithelia, such as the trachea, where a cell type termed *brush cells* has been described, which are likely chemoreceptive and make contact with nearby sensory nerve fibers (Saunders et al, 2013). In addition, there are also reports that have identified and characterized functional properties of sacral afferents responding to flow through the urethra (Snellings et al, 2012). These are important observations whereby properties of these flow-responsive afferents seem to parallel those of cutaneous afferents. This could be important in terms of restoration of bladder emptying after spinal cord injury.

Modulators of Afferent Sensitivity. A number of parameters including stimulus-response function can be used to define the features of the various subpopulations of afferents that supply the LUT. The relationship between stimulus and response can be altered or modified according to the mechanical and chemical environment of the sensory ending. For example, bladder contractions can distort the afferent ending, whereas connective tissue elements will transmit or dissipate stimulus energy within the tissue, determining whether a response is rapidly or slowly adapting to maintained stretch. Similarly, a number of chemical mediators released from a variety of cells within the bladder wall, such as the urothelium and underlying lamina propria, will influence afferent firing.

Many mediators are released during inflammation, injury and ischemia, as well as from a number of cell types such as mast cells, fibroblasts, and neurons. Some mediators act directly on sensory nerve terminals, whereas others act indirectly, causing release of yet other agents from nearby cells. Thus, this can lead to augmented sensitivity of nerve endings to both mechanical and chemical stimuli and may also contribute to chronic pain states. Examples of local mediators include neurotrophins, purines, proteases, prostanooids, and cytokines. They produce their effects on visceral afferent nerves by three distinct processes. First, they can act directly, by opening ion channels on the nerve terminals. Second, they can sensitize endings without causing direct stimulation but causing hyperexcitability to other chemical and mechanical stimuli. Third, as is the case with neurotrophins, they can change the phenotype of the afferent nerve over long periods. For example, they may alter expression of channels, receptors, or mediators in the sensory neuron (Vergnolle, 2008). The result of sensitization is a leftward shift in the stimulus-response function. This means that for any given level of stimulation, a greater afferent barrage is generated. Peripheral sensitization normally develops rapidly and is relatively short-lived. However, in the presence of maintained injury or inflammation, the sensitization can be prolonged by changes in gene expression. Genes influenced in this way include those that determine the amount and pattern of neurotransmitter release by central nerve terminals in the brain and spinal cord. This alters the way that sensory signals are processed within the CNS and contributes to central sensitization (Woolf, 2011).

In contrast, ineffective or inefficient bladder emptying may be caused by a number of changes including damage or injury to bladder (afferent) pathways. Although mechanisms underlying detrusor underactivity are not well explored or defined, conditions including diabetes mellitus, classically referred to as a *diabetic cystopathy*, have been linked with impaired sensory function and increased residual urine (Ellenberg, 1980; Xiao et al, 2013). A number of factors including ischemia, altered glucose metabolism, and/or free radical formation may play a role in diabetic neuropathy and decreased sensation. Studies in aged rats have revealed a decreased afferent sensitivity to changes in bladder volume and a decreased level of afferent neuropeptide expression (Hotta et al,

1995; Mohammed and Santer, 2002). Also, studies in humans have revealed an age-related decreased response to bladder filling in brain regions that play a role in bladder sensation (Griffiths et al, 2007). Therefore, decreased afferent sensitivity or excitability in a number of conditions in addition to normal aging may be an important factor leading to impaired voiding (Smith, 2010; Miyazato et al, 2013).

Nitric Oxide. NO has been identified as a major inhibitory transmitter mediating relaxation of the urethral smooth muscle during micturition (Andersson et al, 1992; Andersson, 1993; Andersson and Persson, 1995; Bennett et al, 1995). In addition, NO is also involved in controlling bladder afferent nerve activity. Inhibitors of NOS, given systemically or intrathecally, do not affect normal micturition in conscious or anesthetized rats. However, DO that accompanies irritation is ameliorated by spinal application of NOS inhibitors (Rice, 1995; Kakizaki and de Groat, 1996; Lagos and Ballejo, 2004). Aizawa and colleagues (2011) examined the effect of NO on sensory signaling by directly recording afferent activity arising from the bladder in vivo. Release of NO can be inhibited using nonmetabolizable analogs that compete with L-arginine as substrate for NOS. On such inhibitor, L-NAME, increased the afferent response to bladder filling by about 50%, which was reversed by activation of NO pathways with L-arginine. These data suggest that NO is able to inhibit afferent activity, an observation consistent with earlier cystometric analysis of the effect of activating the NO pathway (Ozawa et al, 1999). In addition to studying NO mechanisms in the normal bladder, Aizawa and colleagues also showed that application of L-arginine significantly inhibited hypersensitivity induced by the cyclophosphamide metabolite acrolein, which is used experimentally as a model for BPS/IC.

The actions of NO are mediated through elevation of the intracellular second messenger cGMP (Fig. 69-27). The second messengers cAMP and cGMP are synthesized from the corresponding nucleoside triphosphates by their respective membrane-bound or soluble adenylate or guanylate cyclases. cAMP and cGMP are inactivated by phosphodiesterases (PDE) by hydrolytic cleavage of the 3'-ribose phosphate bond. Therefore the level of intracellular second messengers can be regulated by PDE isoenzymes (Truss et al, 1999, 2001). For example, PDE5 terminates the action of NO, and PDE inhibitors can be used therapeutically to prolong the action of NO at a number of sites including the bladder, prostate, and blood vessels. Behr-Roussel and colleagues found that inhibition of PDE5 attenuated bladder afferent activity in a rat model of spinal cord injury (Behr-Roussel et al, 2011). Thus, in addition to an important role for PDEs in regulation of smooth muscle tone, available data suggest that these agents might represent a target for treatment of hypersensitivity disorders of the bladder such as BPS/IC and OAB.

Purinergic Signaling. It is well established that the urothelium releases ATP in response to stretch and that this acts in a paracrine fashion to influence the function of myofibroblasts and bladder afferent nerves (Fig. 69-28). P2X₂ and P2X₃ receptors are expressed on unmyelinated afferent fibers innervating the bladder, and thus the hypothesis has been put forward that mechanosensitivity, at least in those afferents in proximity to the urothelium, involves ATP release by stretch and activation of P2X₂ and P2X_{2/3} receptors on the afferents (Ferguson et al, 1997; Vlaskovska et al, 2001). In the normal bladder, it is believed that a balance between the excitatory effects of ATP and inhibitory effects of NO may determine micturition thresholds and urinary frequency and that this balance may be disturbed in bladder disorders. Elevated ATP levels have been demonstrated in patients with DO and BPS/IC (Kumar et al, 2007). Munoz and colleagues, using a rat model of DO (diabetic bladder), found increased levels of ATP but normal levels of NO (Munoz et al, 2010). Conversely in an underactive bladder model induced by chronic sugar intake, NO levels were increased whereas ATP remained normal. This suggests that the balance between ATP and NO is altered in bladder dysfunction.

Transient Receptor Potential Cation Channels. A number of different members of the transient receptor potential (TRP) channel family are expressed in the bladder, mostly in association with

Figure 69-27. Schematic diagram of the cyclic nucleotide signaling pathways. Stretch stimuli, or acetylcholine release, increase internal Ca^{2+} levels in nitric oxide synthase (NOS)-expressing urothelial cells. NOS produces nitric oxide (NO), which signals to detrusor smooth muscle cells. NO is thought to have a modulatory role in the lower urinary tract, including the relaxation of urethral smooth muscle, modulation of neurotransmitter release from efferent nerves, regulation of urothelial permeability, and modulation of afferent nerve activity. Moreover, a pathophysiologic role of NO has been suggested because injury or chronic inflammation can upregulate the expression of inducible NOS. Guanylyl cyclases located in the cytoplasm or plasma membrane synthesize cyclic guanosine monophosphate (cGMP) in response to NO or C-like natriuretic peptide (CNP), respectively. Cyclic adenosine monophosphate (cAMP) is synthesized by adenylyl cyclases, either associated with G protein-coupled receptors in the plasma membrane, or in the cytoplasm. Membrane-associated adenylyl cyclases are activated by guanosine triphosphate (GTP)-bound G_α and forskolin, whereas cytoplasmic adenylyl cyclases are regulated by HCO_3^- and Ca^{2+} but insensitive to forskolin or activated G_α . cAMP and cGMP are hydrolyzed to AMP and GMP, respectively, by phosphodiesterases (PDEs). ACh, acetylcholine; pAC, particulate (plasma membrane) adenylyl cyclase; pGC, particulate (plasma membrane) guanylyl cyclase; sAC, soluble (cytoplasmic) adenylyl cyclase; sGC, soluble guanylyl cyclase. (From Rahnama'i MS, Ückert S, Hohnen R, et al. The role of phosphodiesterases in bladder pathophysiology. *Nat Rev Urol* 2013;10:414–24.)

sensory nerve fibers involved in mechanotransduction and nociception. TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1 are expressed in varying levels within the bladder. TRPV1, the most extensively studied TRP channel, is expressed on capsaicin-sensitive afferent pathways, predominantly C-fiber nociceptors, and responds to increases in temperature to the noxious range ($>43^\circ\text{C}$) and to protons, suggesting that it functions as a transducer of painful thermal stimuli and acidity in vivo. Thus, C fibers signal inflammatory or noxious events in the bladder. TRPV1 has been shown to play an integral role in modulating the excitability of bladder afferents and the generation of hypersensitivity, induced by bladder inflammation (Birder et al, 2002; Apostolidis et al, 2005a). It is through desensitization of this receptor that agents such as resiniferatoxin (RTX) act to treat symptoms in OAB (Kissin and Szallasi, 2011). TRPV1 is predominantly expressed on sensory nerves and has been identified within nerve plexuses running in both the muscle layer and suburothelium as well as within the urothelium itself.

RTX is the principal active ingredient in the drug euphorbium, which is derived from the air-dried latex (resin) of the cactus-like plant *Euphorbia resinifera*. In 1975 the principal active ingredient in euphorbium was isolated and named *resiniferatoxin* (Hergenhahn et al, 1975). In 1989, RTX was recognized as an ultrapotent analog of capsaicin; however, it has unique pharmacologic effects as well (Szallasi and Blumberg, 1990), such as desensitization without prior excitation of the pulmonary chemoreflex pathway (Szolcsanyi,

1990). In patients with spinal cord injury-induced DO, clinical response to intravesical therapy with RTX showed changes in nerve fiber staining as well as marked improvements on cystometry and other parameters (Brady et al, 2004). Furthermore, it has also been shown that intravesical application of high-dose capsaicin as well as RTX is effective for treating painful symptoms in IC patients (Lazzeri et al, 1996, 2000), although a prospective, randomized clinical trial using intravesical RTX application showed no effect in patients with IC (Payne et al, 2005).

TRPV4 is a member of vanilloid TRPV channels and a nonselective cation channel activated by mechanical pressure, osmolarity (hypotonicity), moderate warmth ($>27^\circ\text{C}$), and chemical stimuli such as phorbol esters. Interest in TRPV4 has been fueled by the observation of impaired voiding behavior in knockout mice (Gevaert et al, 2007). This channel shows mechanosensitivity and is proposed to play a role in the micturition reflex by activating C-fiber afferents (Aizawa et al, 2012). However, the site of action of TRPV4 agonists may in fact be the urothelium, which expresses the TRPV4 channel (Birder et al, 2007a), particularly in association with adherence junctions, where they may be preferentially activated by stretch and lead to the release of ATP (Yamada et al, 2009). Inhibition of TRPV4 has recently been shown to improve symptoms in a model of experimental cystitis (Everaerts et al, 2010).

TRPA1 is the only member of the ankyrin TRP channel and a receptor for several pungent chemicals that evoke pain, such as allyl

Figure 69-28. Morphology and wiring of the lower urinary tract (LUT). In the LUT, adenosine triphosphate (ATP) (shown as blue triangles) is present in large extracellular concentrations, is released by various cells including epithelia, fibroblasts, and smooth muscles, and can activate C-fiber afferent and promote sensitization. Release of ATP is augmented in conditions of stress, injury, inflammation, and infection. (From Ford AP, Udem BJ. The therapeutic promise of ATP antagonism at P2X3 receptors in respiratory and urological disorders. *Front Cell Neurosci* 2013;7:267.)

isothiocyanate (the pungent compound in mustard oil), allicin (garlic), cinnamaldehyde (in cinnamon), and acrolein (a metabolite of cyclophosphamide). TRPA1 also functions as a receptor-operated channel that can be activated by growth factors or proinflammatory peptides such as bradykinin, which increases intracellular Ca^{2+} levels using G protein-coupled receptors. TRPA1 is also expressed in the bladder and is particularly associated with C-fiber endings in the suburothelium that co-localize calcitonin gene-related peptide (CGRP). Agonists acting at the receptor cause bladder overactivity and are suggested to play a role in mechanotransduction and in signaling pain. TRPA1 has also been demonstrated in the urothelium at both transcriptional and protein levels. Expression is increased in a spinal cord injury model, and both pharmacologic blockade and RNA knockdown of TRPA1 were effective in normalizing bladder reflex function (Andrade et al, 2011).

TRPM8 is a member of the temperature-sensitive TRP channels that responds to cold temperature of less than 23°C . Pharmacologic agents that evoke cool sensation, such as menthol and ilicin, can activate TRPM8. Interest in its role in the bladder stems from the observation that instillation of cold saline into the bladder elicits a contractile response (at pressures or volumes below the threshold for normal voiding). This response to a cooling stimulus (which has been referred to as the *bladder cooling reflex*) was originally thought to indicate a supraspinal neurologic lesion, and the test (termed the *ice-water test*) has been used in the diagnosis of bladder disorders such as OAB and BOO (Chai et al, 1998). Expression of TRPM8 has been identified on bladder afferent fibers and on the cell bodies in the DRG where it co-localizes with nociceptive

markers such as CGRP and IB4 (Hayashi et al, 2009a). Previously Lashinger and colleagues (2008) showed that application of a TRPM8 channel blocker decreased voiding frequency and abdominal motor responses in the rat, suggesting that in addition to cold sensing, TRPM8 may also be involved in the afferent control of micturition and nociception.

Cannabinoids. The multicenter Cannabinoids in Multiple Sclerosis (CAMS) study reported that the use of cannabis-based extracts significantly improved symptoms of urge incontinence and DO in patients with multiple sclerosis. This observation has provoked interest in the study of expression and function of cannabinoid (CB) receptors in the bladder. In the human bladder, both receptors could be identified in the urothelium and detrusor, where CB1 receptors were more abundant than CB2 (Tyagi et al, 2009). In patients with BPS/IC and IDO, a significant increase in nerve fibers expressing CB1 in the urothelium was observed, strongly suggesting a role for CB1 in OAB (Mukerji et al, 2010). Functional experiments also found a reduction in distention-evoked afferent firing in response to application of a CB1 agonist. In particular, high-threshold afferents typically associated with noxious stimuli were directly affected. In contrast, Gratzke and colleagues (2009) found CB2 receptors predominated in the urothelium and suburothelium and on sensory nerve fibers and found that CB2 agonists inhibited nerve-induced contractions of the bladder, providing evidence that CB2 receptors are important in micturition. Taken together, these studies suggest that CB receptors in the bladder may have a modulatory role in sensory afferent signaling, a greater understanding of which could lead to new therapeutic strategies for treatment of bladder disorders.

Pelvic Organ Interactions: Crosstalk between Bladder and Bowel. Patients with irritable bowel syndrome (IBS) often report LUT symptoms including nocturia, frequent and urgent micturition, and incomplete emptying (Whorwell et al, 1986). The counterpart is also true with patients with BPS/IC who have bowel symptoms (Alagiri et al, 1997). These observations are consistent with the concept of cross-organ sensitization, which extends to different abdominal and pelvic structures and contributes to a more generalized chronic pelvic pain syndrome (Brumovsky and Gebhart, 2010). In experimental models, colonic inflammation has been shown to lead to increased frequency of bladder contractions and altered micturition reflexes (Pezzone et al, 2005). Similarly, experimental bladder inflammation has been reported to sensitize the bowel to distention (Bielefeldt et al, 2006). Such cross-organ sensitization has also been demonstrated among the uterus, pelvic urethra, and vagina. In men there is the potential for cross-organ sensitization between the prostate and other pelvic organs.

The mechanisms underlying cross-organ sensitization have not been fully elucidated, but there are potentially several levels at which the sensory innervation to the different pelvic structures can interact. In terms of peripheral mechanisms there is evidence that afferent fibers branch extensively to innervate multiple target structures. Axonal tracing studies using different retrograde tracers injected into the bladder and bowel reveal a number of DRG neurons carrying both labels, although the numbers are low. Similarly, dichotomizing afferents have been shown to innervate the colon and uterus with DRGs expressing TRPV1 and P2X₃ receptors, implying a role in nociception. Sensitization of the endings in one organ by local inflammation would likely affect overall sensitivity after upregulation in excitability in all terminal receptive fields. Central sensitization may also contribute to cross-organ sensitization. Excitability of spinal neurons receiving afferent input from the bladder has been shown to respond to afferent input from other pelvic structures such as the colon (Fig. 69-29) (Malykhina, 2007; Clemens et al, 2008). Second-order neurons in the spinal cord therefore receive convergent input from various visceral structures as well as somatic inputs. The latter explains the phenomenon of referred pain wherein sensations from the viscera are experienced in the associated somatic sensory field, the classic example being angina. Such viscerosomatic convergence has been extensively investigated, and only recently has viscerovisceral referral received attention. Nevertheless, convergent inputs would explain the poor

Figure 69-29. Schematic representation of convergent afferent pathways. 1, Convergence of sensory neural pathways within a dorsal root ganglion (red route). The propagation of noxious stimulus from a diseased pelvic organ to a normal adjacent structure occurs via dichotomizing afferents as a result of an “axon-reflex” mechanism. Axon-reflex–antidromic propagation of action potentials (APs) from dorsal root ganglion to the periphery. 2, Convergence of afferent information in the spinal cord (blue route). DRR refers to dorsal root reflexes (antidromic conduction via sensory fibers from the spinal cord to the periphery). Note that an output neuron belongs to the population of intermediolateral neurons (not motoneurons) localized mostly in laminae VI to VII. 3, Convergence of afferent inputs from two different pelvic organs in the brain (green route). Convergent neurons within the dorsal root ganglion, in the spinal cord, and in the brain are shown by star symbol. Orthodromic propagation of APs from pelvic organs to the points of convergence is depicted by solid lines and arrows in respective color for each route. Anterograde AP propagation from the brain, the spinal cord, and the dorsal root ganglion to the periphery is shown by dotted lines. (From Malykhina AP. Neural mechanisms of pelvic organ cross-sensitization. *Neuroscience* 2007;149:660–72.)

localization of pelvic pain and the difficulty in diagnosis and treatment.

Efferent Pathways to the Bladder

Three main neural pathways regulate LUT efferent activity: (1) Sacral parasympathetic (pelvic) nerves provide excitatory input to the bladder; (2) thoracolumbar sympathetic (hypogastric) nerves provide inhibitory input to the bladder and excitatory input to the bladder neck and urethra; and (3) sacral somatic (pudendal) nerves innervate the striated muscles of the sphincters and pelvic floor (Fig. 69-30) (Kluck, 1980). Parasympathetic postganglionic fibers termi-

KEY POINTS: AFFERENT PATHWAYS

- Studies of the properties of bladder afferents in the pelvic nerve, particularly in the rat, indicate that in-series tension receptors, volume receptors, and silent afferents (including nociceptors) are present.
- Intravesical irritant chemicals reduce the pressure thresholds of most of these endings, including the high-threshold receptors.
- A substantial proportion of the C-fiber afferent population is silent (i.e., insensitive to normal distention). However, these fibers become mechanosensitive after the action of various chemical mediators.
- During inflammation and possibly other pathologic conditions, there is recruitment of mechanosensitive C fibers that form a new functional afferent pathway. This is the rationale for intravesical C-fiber neurotoxin capsaicin and RTX therapy (Chancellor and de Groat, 1999).

nate predominantly at the detrusor muscle and release ACh, resulting in detrusor contraction during voiding. Studies in animals have shown that sympathetic postganglionic fibers release noradrenaline (NA) and contribute to bladder relaxation during storage (via stimulation of β -adrenergic receptors expressed in detrusor).

Terminal Nerve Fibers. Smooth muscle cells in the bladder are grouped into fascicles, several of which make up a muscle bundle. They receive a dense innervation, which runs in line with the axis of the fascicle and is derived from coarse nerve trunks in the connective tissue around the fascicles and bundles. This innervation mediates the widespread coordinated detrusor contraction accompanying voiding. The nerve supply is illustrated in Figure 69-6 (Maas et al, 2005), and the anatomic relationship between the preterminal innervation and the muscle fascicles has been described in a serial sectioning study in the human bladder (Drake et al, 2003).

The majority of nerves innervating the detrusor express acetylcholinesterase and vesicular acetylcholine transferase (VACHT) (Ek et al, 1977; Dixon et al, 1983; Maas et al, 2005) and are thought to be parasympathetic. EFS studies have been used to elucidate the neurotransmitter content from muscle strips (with or without the mucosa). ACh and ATP appear to provide the majority of the excitatory input, because EFS responses are blocked by muscarinic receptor antagonists combined with purinergic antagonists. Both transmitters are released in the innervated muscle layer and persist after mucosal removal. Apart from ACh and ATP, there are additional substances present in parasympathetic efferents (vasoactive intestinal polypeptide [VIP], NOS, galanin), which allow immunohistochemical subclassification of nerve fibers and raise the question as to whether additional transmitters (other than ACh and ATP) have a role in normal micturition function or disease pathophysiology. In addition, cholinergic nerves are also present in the suburothelium, where most also contain neuropeptide Y (NPY) and tyrosine hydroxylase and some also contain NOS. In the muscle of the trigone, the most common axons contain both VIP and NPY, with noradrenergic axons forming only a sparse supply. Indeed, noradrenergic neurons are rare in the detrusor and absent in the urothelium (Wanigasekara et al, 2003).

Spinal Ascending and Descending Influences:

Transmitters

Glutamate. Glutamate is present in the terminals of primary afferent neurons in the spinal cord along with interneurons and fibers originating in the medulla oblongata. In general, glutamatergic neurons tend to be excitatory, contrasting with generally inhibitory effects of glycinergic neurons; however, excitatory and inhibitory effects of transmitters can be reversed by the nature of the postsynaptic neuron. Thus, glutamatergic neurons can indirectly have an inhibitory effect if an inhibitory neuron is interposed before the ultimate target (de Groat and Yoshimura, 2001). Glutamate acts on spinal neurons through a variety of receptor subtypes

Figure 69-30. Mechanism of storage and voiding reflexes. **A, Storage reflexes.** During the storage of urine, distention of the bladder produces low-level bladder afferent firing. Afferent firing, in turn, stimulates the sympathetic outflow to the bladder outlet (base and urethra) and pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways and represent “guarding reflexes,” which promote continence. Sympathetic firing also inhibits detrusor muscle and transmission in bladder ganglia. **B, Voiding reflexes.** At the initiation of micturition, intense vesical afferent activity activates the brainstem micturition center, which inhibits the spinal guarding reflexes (sympathetic and pudendal outflow to the urethra). The pontine micturition center also stimulates the parasympathetic outflow to the bladder and internal sphincter smooth muscle. Maintenance of the voiding reflex is through ascending afferent input from the spinal cord, which may pass through the periaqueductal gray matter (PAG) before reaching the pontine micturition center.

including *N*-methyl-D-aspartate (NMDA) receptors, which are important in controlling polysynaptic reflex pathways at the lumbosacral levels (Fig. 69-31). With aging, there is a decrease in the density of glutamatergic synaptic inputs, which may influence urinary tract function (Ranson et al, 2007).

Glycine and γ -Aminobutyric Acid. Glycinergic and GABAergic interneurons have a major role in neural control processes mediating bladder function (Shefchyk, 2002). Glycinergic and GABAergic projections to the lumbosacral cord inhibit the micturition reflex and also inhibit glutamatergic neurons (Miyazato et al, 2013). Clinically, DO can be inhibited by GABA receptor activation (Miyazato et al, 2008b, 2008c). Rectal distention prolongs the interval, decreases the amplitude, and shortens the duration of bladder contractions in rats; this effect is not seen after simultaneous intrathecal injection of low-dose strychnine (a selective glycine-receptor antagonist) and bicuculline (GABA-A receptor antagonist), suggesting that the inhibitory rectovesical reflex involves glycinergic and GABAergic mechanisms in the lumbosacral spinal cord, which may be synergistic (Miyazato et al, 2004).

Serotonin. Spinal reflex circuits involved in voiding function have a dense serotonergic (5-hydroxytryptamine [5-HT]) innervation (de Groat, 2002). Immunocytochemical studies in rats, cats, and primates show that lumbosacral sympathetic and parasympathetic autonomic nuclei receive serotonergic inputs from the raphe nuclei

(Mizukawa, 1980; Kojima et al, 1983; Skagerberg and Bjorklund, 1985; Rajaofetra et al, 1992). Activation of the central serotonergic system can suppress voiding by inhibiting the parasympathetic excitatory input to the urinary bladder, and 5-HT elicits a prolonged activation of thoracic sympathetic preganglionic neurons. Stimulation of the raphe nuclei in the cat inhibits reflex bladder activity (McMahon and Spillane, 1982; Chen et al, 1993; Sugaya et al, 1998). 5-HT_{1A} and 5-HT₂ receptors are present in the sacral parasympathetic nucleus. However, in different species, serotonin (5-HT) may have varying functions in the central nervous control of bladder activity. For example, activation of 5-HT_{1A} receptors facilitates reflex bladder activity in rats (Lecci et al, 1992; de Groat, 2002) and has been used to reverse the effects of diabetes mellitus (Gu et al, 2012).

Duloxetine, a combined norepinephrine and 5-HT reuptake inhibitor (Sharma et al, 2000), has been shown, in a bladder-irritated model, to increase the neural activity of both the urethral sphincter and the bladder (Thor and Katofiasc, 1995; Thor and Donatucci, 2004). Duloxetine appears to have effects on both the bladder and the sphincter and has been proposed for treatment of both stress incontinence and urgency incontinence (Cannon et al, 2003; Thor and Donatucci, 2004). Duloxetine increases the neural activity to the EUS and decreases bladder activity through effects on the CNS in cats (Thor and Donatucci, 2004). In a rat study, duloxetine also enhances the urethral continence reflex

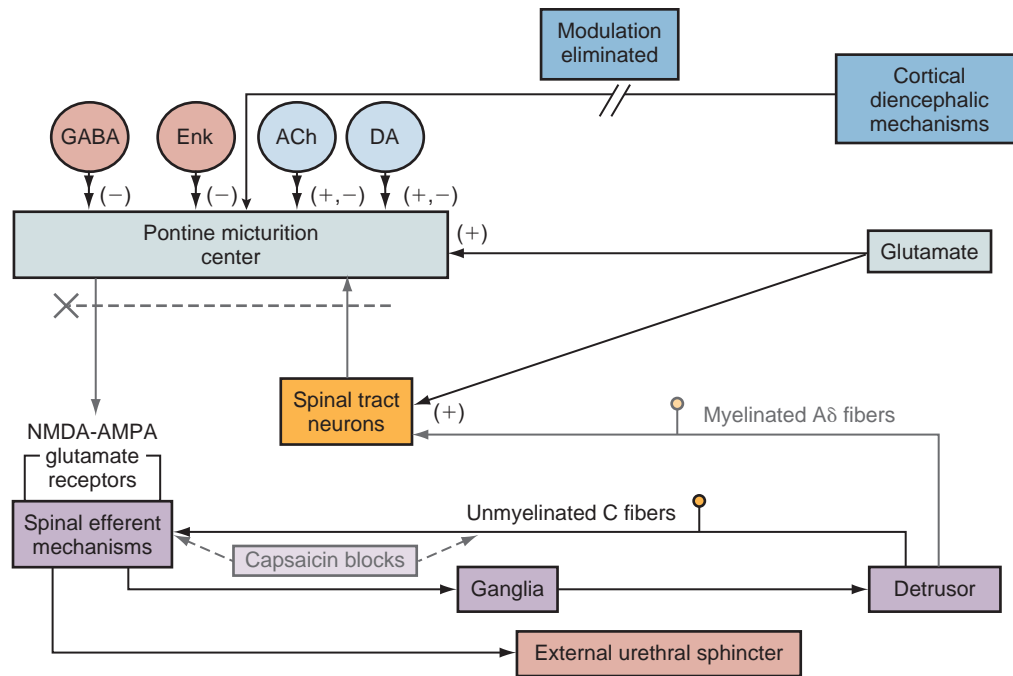

Figure 69-31. Diagram of the central reflex pathways that regulate micturition in the cat. Normally, micturition is initiated by a supraspinal reflex pathway passing through the pontine micturition center (PMC) in the brainstem. The pathway is triggered by myelinated afferents (A δ) connected to tension receptors in the bladder wall (detrusor). Spinal tract neurons carry information to the brain. During micturition, pathways from the PMC activate the parasympathetic outflow to the bladder and inhibit the somatic outflow to the urethral sphincter. Transmission in the PMC is modulated by cortical-diencephalic mechanisms. Interruption of these mechanisms leads to bladder instability. In spinal cord-transected animals, connections between the brainstem and the sacral spinal cord are interrupted and micturition is initially blocked. In animals with chronic spinal cord injury, a spinal micturition reflex emerges that is triggered by unmyelinated (C-fiber) bladder afferents. The C-fiber reflex pathway is usually weak or undetectable in animals with an intact nervous system. Stimulation of the C-fiber bladder afferents by instillation of ice water into the bladder (cold stimulation) activates voiding reflexes in patients with spinal cord injury. Capsaicin (20 to 30 mg/kg subcutaneously) blocks the C-fiber reflexes in cats with chronic spinal cord injury but does not block micturition reflexes in intact cats. Intravesical capsaicin also suppresses bladder instability and cold-evoked reflexes in patients with neurogenic bladder dysfunction. Glutamic acid is the principal excitatory transmitter in the ascending and descending limbs of the micturition reflex pathway, as well as in the reflex pathway controlling sphincter function. Glutamate acts on both *N*-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamatergic receptors. Other neurotransmitters that regulate transmission in the micturition reflex pathway include γ -aminobutyric acid (GABA), enkephalins (Enk), acetylcholine (ACh), and dopamine (DA). Acetylcholine and dopamine have both excitatory and inhibitory effects on the pathway: excitatory (+) and inhibitory (-) synapse.

during sneezing as evidenced by an increase in sneeze-induced pressure responses at the middle urethra, although the effect appears to be mainly mediated by α_1 adrenoceptors (Miyazato et al, 2008a).

Adrenergic Transmitters. Descending catecholaminergic neurons are primarily located in the upper medulla or pons (Ranson et al, 2003). In clinical use, nonselective α_1 -adrenergic antagonists influence urine flow and LUTS; the two effects probably occur by different mechanisms, and central or peripheral locations may be responsible (Somogyi et al, 1995). Reflex bladder activity is modulated by at least two spinal α_1 -adrenergic mechanisms. Firstly, there is inhibitory control of reflex bladder contractions, probably by modulation of afferent processing. Second, there is excitatory modulation of the amplitude of bladder contractions as a result of regulation of the descending glutamatergic limb of the spinobulbospinal bladder reflex pathway (de Groat et al, 1999; Yoshiyama et al, 2000). α_{1A} Adrenoceptors constitute 70% and α_{1B} adrenoceptors constitute 30% of the α -adrenergic receptors in the rat lumbar spinal cord (Wada et al, 1996), whereas α_{1D} adrenoceptors do not appear to have a significant role.

Blood pressure, vascular resistance, and tissue blood flow are also regulated by α -adrenergic receptors. Aging is thought to affect pelvic blood flow and thus bladder function. Pharmacologic blockade of the vascular α_{1B} adrenoceptor may increase pelvic blood flow and contribute to an improvement in bladder dysfunctions associated with aging and/or hypertension (Yono et al, 2011). β_3 Adrenoceptors, although well documented peripherally, are also present at a number of sites peripherally as well as in the rat sacral spinal cord. A number of studies have demonstrated that these agonists (via effects on bladder afferents and detrusor smooth muscle) may be a promising treatment for OAB (Chapple et al, 2014).

Purinergic Transmitters. ATP acting via purinergic receptors modulates bladder function mediated by both afferent and efferent pathways involved in urine storage and emptying. ATP is released together with NA and NPY from sympathetic nerves. It is also released as a cotransmitter with ACh from parasympathetic nerves supplying the bladder. Cotransmission likely offers subtle, local variations in neurotransmission and neuromodulation

mechanisms (Burnstock, 2009). Purinergic contribution to parasympathetic stimulation has been shown to exist in a variety of species including rat, rabbit, and guinea pig (Burnstock et al, 1972; Chancellor et al, 1992; Burnstock, 1996). In contrast, there is less evidence that purinergic neurotransmission exists in humans, at least regarding normal responses to stimulation, but it may play a role in pathologic conditions such as DO or BOO (Palea et al, 1993; Burnstock, 2001b; O'Reilly et al, 2001a).

ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G protein–coupled receptor family (P2Y) (Inoue and Brading, 1990; Inoue and Gabella, 1991; McMurray et al, 1997). Seven P2X subtypes and eight P2Y subtypes have been identified. Analysis of the structure-activity relationships of a series of excitatory purinergic agonists on the guinea pig bladder revealed an order of potency consistent with P2X₁ or P2X₂ receptors (Burnstock, 2001a; Zhong et al, 2001). In other species various studies suggested that multiple purinergic excitatory receptors are present in the bladder (Burnstock, 2001b).

Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X₁ receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder (Lee et al, 2000). The predominant expression of P2X₁ receptors has also been confirmed in the human bladder (O'Reilly et al, 2001a, 2001b). Investigators also found that the amount of P2X₁ receptors was increased in the obstructed bladder compared with the control bladder, suggesting upregulated purinergic mechanisms mediating OAB due to BOO (O'Reilly et al, 2001a).

KEY POINTS: SPINAL CIRCUITRY NEUROTRANSMITTERS

- Glutamate plays an important role in the spinal efferent circuitry supporting micturition.
- The spinal noradrenergic system, mediated by α_1 adrenoceptors, has a modulatory role in controlling micturition by inhibiting afferent inputs from the bladder and facilitating the descending limb of the spinal micturition reflex to increase bladder contractility.
- Transmitters such as 5-HT, purines, glycine, and GABA appear to selectively modulate the volume threshold by actions in the sacral spinal cord. The role of other potential excitatory transmitters remains to be examined.
- These mechanisms seem to be favorable for development of novel drug therapies.
- Glutamate appears to be involved as an excitatory transmitter in the supraspinal circuitry controlling micturition.
- Glutamate may also be a mediator of DO after neural injury.
- Several substances can exert significant modulatory influences on the supraspinal circuits (see Fig. 69-31) and can have dramatic influences on micturition.
- The receptors for these substances represent potential sites for therapeutic intervention.

Reflex Circuitry Controlling Continence and Micturition. Multiple reflex pathways organized in the brain and spinal cord mediate coordination between the urinary bladder and the urethra. The central pathways controlling LUT function are organized as simple on-off switching circuits (Fig. 69-32) that maintain a reciprocal relationship between the urinary bladder and the urethral outlet (de Groat, 1975; de Groat et al, 1993). Some reflexes promote urine storage, whereas others facilitate voiding (see Fig. 69-30). It is also possible that individual reflexes might be linked together in a serial manner to create complex feedback mechanisms. For example, the bladder-to-EUS guarding reflex that triggers sphincter contractions during bladder filling could, in turn, activate sphincter muscle afferents that initiate an inhibition of

Figure 69-32. Diagram illustrating the anatomy of the lower urinary tract and the “switchlike” function of the micturition reflex pathway. During urine storage, a low level of afferent activity activates efferent input to the urethral sphincter. A high level of afferent activity induced by bladder distention activates the switching circuit in the central nervous system (CNS), producing firing in the efferent pathways to the bladder, inhibition of the efferent outflow to the sphincter, and urine elimination.

the parasympathetic excitatory pathway to the bladder. Thus a bladder-to-sphincter-to-bladder reflex pathway could, in theory, contribute to the suppression of bladder activity during urine storage. Alterations in these primitive reflex mechanisms may contribute to neurogenic bladder dysfunction. Direct activation of these reflexes by electric stimulation of the sacral spinal roots very likely contributes to therapeutic effects of sacral nerve root neuromodulation (Dijkema et al, 1993; Chancellor and Chartier-Kastler, 2000).

Storage Phase of the Bladder. Intravesical pressure measurements during bladder filling in both humans and animals reveal low and relatively constant bladder pressures when bladder volume is below the threshold for inducing voiding (Fig. 69-33). The accommodation of the bladder to increasing volumes of urine is dependent on the intrinsic properties of the vesical smooth muscle and stroma, as well as the quiescence of the parasympathetic efferent pathway (Torrens and Morrison, 1987; de Groat et al, 1993; Yoshimura et al, 2008). In addition, the urothelium also plays an important role in accommodating urine storage via changes in the apical (umbrella) cell membrane and release of a number of neuromediators that can influence bladder smooth muscle tone (Wang et al, 2005). The bladder sympathetic reflex also contributes as a negative feedback or urine storage mechanism that promotes closure of the urethral outlet and inhibits neurally mediated contractions of the bladder during bladder filling (de Groat and Theobald, 1976) (Table 69-3). Reflex activation of the sympathetic outflow to the LUT can be triggered by afferent activity induced by distention of the urinary bladder (de Groat and Theobald, 1976; de Groat et al, 1993). This reflex response is organized in the lumbosacral spinal cord and persists after transection of the spinal cord at the thoracic levels (Fig. 69-34). However, this bladder sympathetic mechanism to suppress bladder contractions during urine storage may be weak in humans, given that bilateral retroperitoneal lymph node dissection, in which the sympathetic chains are destroyed, results in no discernible alteration of filling or storage function in humans.

During bladder filling, the activity of the sphincter electromyogram also increases (see Fig. 69-33), reflecting an increase in efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of urinary continence. Pudendal motoneurons are activated by bladder afferent input (the guarding reflex) (Park et al, 1997), whereas during micturition the motoneurons are reciprocally inhibited (de Groat et al, 1993). EUS motoneurons are also activated by urethral or perineal afferents in the pudendal nerve (Fedirchuk et al, 1992). This reflex may represent, in part, a continence mechanism that is activated by proprioceptive afferent input from the urethra or pelvic

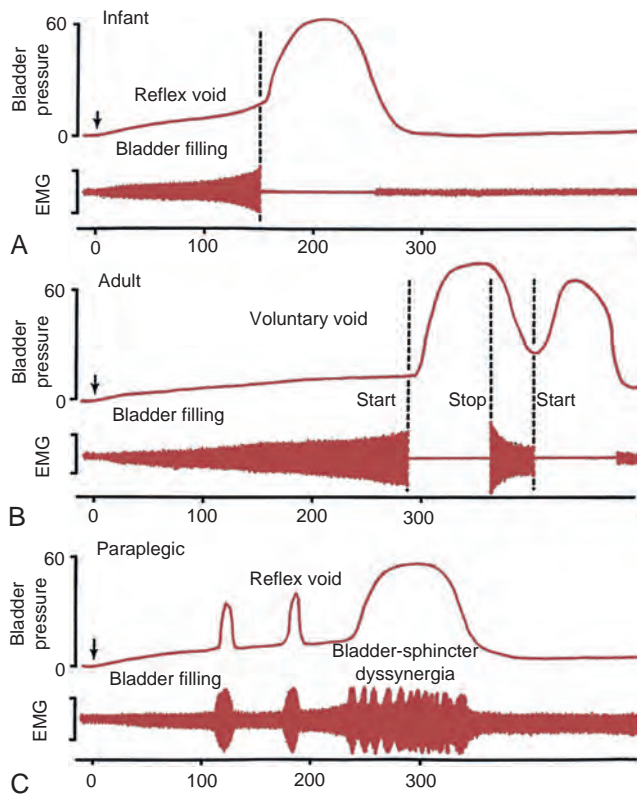

Figure 69-33. Combined cystometrograms and sphincter electromyogram (EMG) comparing reflex voiding responses in an infant (A) and in a paraplegic patient (C) with a voluntary voiding response in an adult (B). The x-axis in all records represents bladder volume in milliliters, and the y-axis represents bladder pressure in centimeters of water and electrical activity of the electromyographic recording. On the left side of each trace, the arrows indicate the start of a slow infusion of fluid into the bladder (bladder filling). Vertical dashed lines indicate the start of sphincter relaxation that precedes by a few seconds the bladder contraction in A and B. In B, note that a voluntary cessation of voiding (stop) is associated with an initial increase in sphincter electromyographic activity followed by a reciprocal relaxation of the bladder. A resumption of voiding is again associated with sphincter relaxation and a delayed increase in bladder pressure. On the other hand, in the paraplegic patient (C), the reciprocal relationship between bladder and sphincter is abolished. During bladder filling, transient uninhibited bladder contractions occur in association with sphincter activity. Further filling leads to more prolonged and simultaneous contractions of the bladder and sphincter (bladder-sphincter dyssynergia). Loss of the reciprocal relationship between bladder and sphincter in paraplegic patients interferes with bladder emptying. (From de Groat WC. Basic neurophysiology and neuropharmacology. In: Abrams P, Khoury S, Wein A, editors. Incontinence. Plymouth [U.K.]: Health Publications; 1999. p. 112.)

floor and that induces closure of the urethral outlet. These excitatory sphincter reflexes are organized in the spinal cord. Inhibition of EUS reflex activity during micturition is dependent, in part, on supraspinal mechanisms, because it is weak or absent in chronically spinalized animals and humans, resulting in simultaneous contractions of bladder and sphincter (i.e., detrusor-sphincter dyssynergia) (Rossier and Ott, 1976; Blaivas, 1982).

Sphincter to Bladder Reflexes. It is well known that stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding function. The inhibition can be induced by activation of afferent input from various sites, including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter (de Groat et al, 1979, 1993, 2001). Electrophysiologic studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the

sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons (de Groat et al, 1982).

On the basis of experiments in the laboratory and the review of medical literature, contractions of the EUS, and possibly other pelvic floor striated muscles, are likely to stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (see Fig. 69-33). A similar inhibitory mechanism has been identified in monkeys by directly stimulating the anal sphincter muscle (McGuire et al, 1983). In monkeys, at least part of the inhibitory mechanism must be localized in the spinal cord, because it persisted in T4 chronically paraplegic animals.

It is well known that stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding function. The inhibition can be induced by activation of afferent input from various sites, including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter (de Groat et al, 1979, 1993, 2001). Electrophysiologic studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons (de Groat et al, 1982).

On the basis of laboratory experiments and review of the medical literatures, it is likely that contractions of the EUS, and possibly other pelvic floor striated muscles, stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (Fig. 69-35). A similar inhibitory mechanism has been identified in monkeys by directly stimulating the anal sphincter muscle (McGuire et al, 1983). In monkeys, at least part of the inhibitory mechanism must be localized in the spinal cord, because it persisted in T4 chronically paraplegic animals.

Somatic to Visceral Reflexes. There is evidence that stimulation of the sacral nerve roots using implanted electrodes (sacral neuromodulation) may be effective in patients with refractory OAB as well as in nonobstructive urinary retention, in patients refractory to conventional methods. Though the specific site of action is still unknown, various mechanisms have been described including the modulation of CNS pathways (including somatic afferent inhibition of sensory processing) and the restoration of brainstem autoregulation (Leng and Chancellor, 2005; Thompson et al, 2010). Although more comprehensive evaluation is needed, another method that has been used as effective treatment for OAB and nonobstructive urinary retention is posterior tibial nerve stimulation (PTNS). Studies in anesthetized cats revealed that continuous tibial nerve stimulation (TNS) inhibited bladder activity that persisted after termination of the stimulus (Tai et al, 2011), suggesting a role for treatment in bladder overactivity. In addition, this group also found evidence that an interaction between opioid and metabotropic glutamate receptor mechanisms may play a role in mechanisms underlying TNS-induced inhibition of bladder overactivity (Matsuta et al, 2013).

Emptying Phase of the Bladder. The storage phase of the bladder can be switched to the voiding phase either involuntarily (reflexively) or voluntarily. The former is readily demonstrated in the human infant or in patients with neuropathic bladder when the bladder wall tension caused by increased volume of urine exceeds the micturition threshold. At this point, increased afferent firing from tension receptors in the bladder reverses the pattern of efferent outflow, producing firing in the sacral parasympathetic pathways and inhibition of sympathetic and somatic pathways. The expulsion phase consists of an initial relaxation of the urethral sphincter (see Fig. 69-33) followed in a few seconds by a contraction of the bladder, an increase in bladder pressure, and the flow of urine. Relaxation of the urethral smooth muscle during micturition is mediated by activation of a parasympathetic pathway to the urethra that triggers the release of NO, an inhibitory transmitter (Andersson, 1993), and by removal of excitatory inputs to the urethra. Secondary reflexes elicited by flow of urine through the urethra facilitate bladder emptying (Torrens and Morrison, 1987; de Groat et al, 1993; Jung et al,

TABLE 69-3 Reflexes to the Lower Urinary Tract

AFFERENT PATHWAY	EFFERENT PATHWAYS	CENTRAL PATHWAY
URINE STORAGE Low-level vesical afferent activity (pelvic nerve)	External sphincter contraction (somatic nerves) Internal sphincter contraction (sympathetic nerves) Detrusor inhibition (sympathetic nerves) Ganglionic inhibition (sympathetic nerves) Sacral parasympathetic outflow inactive	Spinal reflexes
MICTURITION High-level vesical afferent activity (pelvic nerve)	Inhibition of external sphincter activity Inhibition of sympathetic outflow Activation of parasympathetic outflow to the bladder Activation of parasympathetic outflow to the urethra	Spinobulbospinal reflex

Figure 69-34. Diagram showing bladder to urethra reflex pathways. Afferent pathway (dashed line) from the detrusor activates spinal reflex mechanisms that induce firing in somatic cholinergic nerves to the external urethral sphincter, sympathetic adrenergic nerves to the urethral smooth muscle, and cholinergic and nitrergic nerves to the urethral smooth muscle. Bulbospinal pathways from the brain can modulate these spinal reflex mechanisms. ACh, acetylcholine; NEPI, norepinephrine; NO, nitric oxide; +, excitatory mechanism; –, inhibitory mechanism.

1999). These reflexes require the integrative action of neuronal populations at various levels of the neuraxis. The parasympathetic outflow to the detrusor and urethra has a more complicated central organization involving spinal and spinobulbospinal pathways passing through a micturition center in the pons (pontine micturition center [PMC]).

Urethra to Bladder Reflexes. A landmark in the historical progress of neurobiology is the contribution of Barrington. Using his keen observational skills, Barrington (1931, 1941) reported that urine flow or mechanical stimulation of the urethra with a catheter could excite afferent nerves that, in turn, facilitated reflexive bladder contractions in the anesthetized cat (see Fig. 69-35). He proposed that this facilitatory urethra-to-bladder reflex could promote complete bladder emptying. Barrington identified two components of this reflex. One component was activated by a somatic afferent pathway in the pudendal nerve and produced facilitation by a supraspinal mechanism involving the PMC (see Fig. 69-35) (Bar-

rington, 1931). Studies have confirmed the existence of this type of reflex by the pudendal nerve because low-frequency electric stimulation of afferent axons in the pudendal nerve in humans, or the deep perineal nerve (a caudal branch of the pudendal nerve) in cats, can initiate reflexive bladder contractions and voiding (Shefchyk and Buss, 1998; Boggs et al, 2005). The other component was activated by a visceral afferent pathway in the pelvic nerve and produced facilitation by a spinal reflex mechanism (Barrington, 1941).

Studies in the anesthetized rat have also provided additional support for Barrington's findings (Dokita et al, 1991). Measurements of reflexive bladder contractions, under isovolumetric conditions during continuous urethral perfusion (0.075 mL/min), revealed that the frequency of micturition reflexes was significantly reduced when urethral perfusion was stopped or after infusion of lidocaine (1%) into the urethra. Intraurethral infusion of NO donors (S-nitroso-N-acetylpenicillamine [SNAP] or nitroprusside, 1 to 2 mM) markedly decreased urethral perfusion pressure

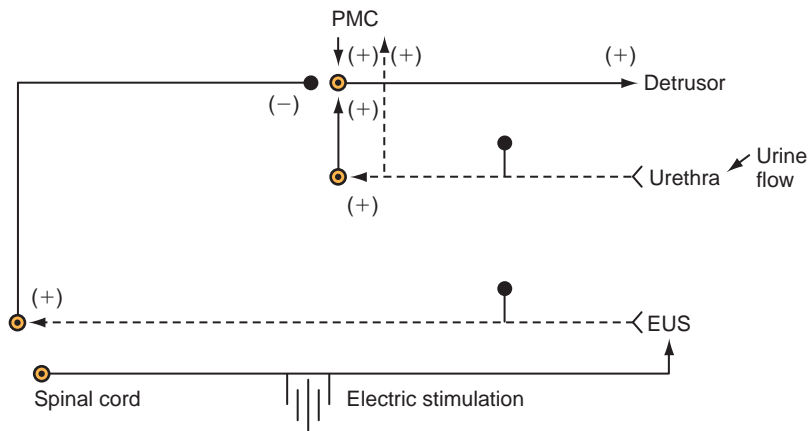

Figure 69-35. Urethra to bladder reflexes. Activity in afferent nerves (dashed lines) from the urethra can facilitate parasympathetic efferent outflow to the detrusor by means of a supra-spinal pathway passing through the pontine micturition center (PMC), as well as a spinal reflex pathway. Afferent input from the external urethral sphincter (EUS) can inhibit parasympathetic outflow to the detrusor through a spinal reflex circuit. Electric stimulation of motor axons in the S1 ventral root elicits an EUS contraction and EUS afferent firing that, in turn, inhibits reflex bladder activity. +, excitatory mechanism; –, inhibitory mechanism.

(approximately 30%) and decreased the frequency of reflex bladder contractions (45% to 75%) but did not change the amplitude of bladder contractions (Fig. 69-36). Desensitization of the urethral afferent with intraurethral capsaicin also dramatically altered the micturition reflex (Fig. 69-37). It was concluded that activation of urethral afferents during urethral perfusion could modulate the micturition reflex in the rat.

Supraspinal Pathways

Pontine Micturition Center and Brainstem Modulatory Mechanisms. The integral role of the brainstem in bladder function was initially realized by the demonstration in cats that micturition was abolished by lesions at the level of the inferior colliculus, whereas lesions anterior to the colliculus facilitated micturition, presumably by removing inhibitory influences (Barrington, 1921, 1925). Anatomic and physiologic studies in both rat and cat have delineated midbrain–pontine–spinal cord circuits in reflexes controlling filling, storing and emptying of the bladder (Fig. 69-38). The roles of pontine nuclei revealed by animal models translate well to humans as indicated by brain imaging during micturition (Fukuyama et al, 1996; Blok et al, 1997; Kershen et al, 2003) and clinical cases showing that specific pontine lesions can result in either bladder continence or incontinence problems (Fukuyama et al, 1996; Sakakibara et al, 1996; Charil et al, 2003).

The dorsal pontine tegmentum has been firmly established as an essential control center for micturition in normal subjects. First described by Barrington (1921), it has subsequently been called the *Barrington nucleus*, the *pontine micturition center* (Blok and Holstege, 1997) or the *M region* (Blok and Holstege, 1996; Holstege et al, 1996) because of its medial location. In 1925 Barrington was the first to describe a pontine control center for micturition in the cat after lesion studies (Barrington, 1921, 1925). This region was better localized to a nucleus in the dorsal pons (now termed the *Barrington nucleus*) using more discrete lesions that abolished micturition and caused urinary retention in cats and rats (Tang, 1955; Satoh et al, 1978). Lesions in humans as a result of stroke or multiple sclerosis in an analogous region similarly result in urinary retention (Komiya et al, 1998).

Physiologic studies have confirmed the role of the Barrington nucleus in micturition. Both electrical and chemical activation of Barrington nucleus neurons in rats and cats initiates bladder contractions and relaxes the urethral sphincter (Holstege et al, 1986; Mallory et al, 1991; Pavcovich and Valentino, 1995; Tanaka et al, 2003). Precise mapping of sites at which chemical stimulation

elicits bladder contractions demonstrates a well-defined area localized to the Barrington nucleus (Pavcovich and Valentino, 1995). Single unit recordings in rat pons revealed three types of responses to bladder contraction: an excitation that occurred only before contraction, an excitation that occurred before and was maintained during contraction, and an inhibition during contraction (Tanaka et al, 2003). Neurons that were activated just before contraction and that maintained activation during contraction were found in Barrington nucleus whereas the other two types of neurons were scattered throughout the pontine tegmentum.

Micturition also requires an inhibition of the urethral sphincter to be coordinated with detrusor contraction. The striated urethral sphincter (rhabdosphincter) is controlled by the interaction between upper motor neurons and the lower motoneurons of the Onuf nucleus. Barrington nucleus neurons do not project to Onuf nucleus. Rather, in the cat a diffuse region ventrolateral to Barrington nucleus, termed the *L-region*, is thought to provide pontine control of sphincter function through its projections to Onuf nucleus (Holstege et al, 1979). For coordination between the detrusor and sphincter, there should be some form of reciprocal communication between these regions. However, a lack of connections between Barrington nucleus and the L-region argue against sphincter regulation by Barrington nucleus through this route (Blok and Holstege, 1999). Rather, it has been proposed that Barrington nucleus indirectly inhibits Onuf nucleus neurons through excitatory projections to GABA premotor interneurons in the dorsal gray commissure (Blok and Holstege, 1999). In addition, Barrington nucleus projections onto inhibitory interneurons located in the intermediolateral cell column at the sacral segmental level have been described and may provide an inhibitory influence over Onuf nucleus; both glycine and GABA are thought to play a role here (Blok and Holstege, 1998; Sie et al, 2001). Together, the anatomic and physiologic findings just described point to Barrington nucleus as being the command center for initiating and orchestrating the act of bladder emptying.

Central Circuitry Regulating Bladder Function by Transneuronal Tracing. Transneuronal retrograde tracing from end organs with pseudorabies virus (PRV) has been an invaluable tool in delineating the central circuitry that regulates visceral function (Loewy, 1998). The population of rat brain neurons labeled from PRV injections in either the bladder wall or urethra of the rat exhibits an overlap and similar time course of labeling, supporting a close coordination of detrusor and urethral muscle function by brain circuits as previously suggested (Nadelhaft et al, 1992; Vizzard et al, 1995; Nadelhaft and Vera, 1996; Marson, 1997). The first neurons

Figure 69-36. Effects of intraurethral S-nitroso-N-acetylpenicillamine (SNAP) on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. **A,** Before treatment. **B,** After intraurethral administration of SNAP (2 mM). Urethral perfusion pressure immediately decreased. In addition, bladder contraction frequency was significantly decreased. The duration of reflexive urethral relaxation was increased. (From Jung SY, Fraser MO, Ozawa H, et al. Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. *J Urol* 1999;162:204–12.)

to be labeled in brain from bladder or urethra and therefore the most direct links to the spinal efferents are the ventral medullary raphe, parapyramidal reticular formation, A5, and Barrington nucleus. The periaqueductal gray (PAG), hypothalamus, and medial preoptic nucleus, which are prominent afferents to Barrington nucleus, are labeled at a slightly later time when the locus ceruleus (LC), cortex, and red nucleus are also labeled. It is interesting to note that PRV labeling from other pelvic viscera including the distal colon yields a similar pattern and time course, suggesting a certain degree of central coordination of these functions (Marson and Carson, 1999; Rouzade-Dominguez et al, 2003).

The PRV studies provide information regarding some hierarchy of neurons that is anatomically linked to the bladder and/or urethra. However, the PRV technique does not imply precise information about connectivity or functionality. This must be delineated by additional tract tracing between putatively connected brain nuclei and physiologic studies. For example, studies in humans indicate that voluntary control of voiding is dependent on connections between the frontal cortex and the septal-preoptic region of the hypothalamus, as well as on connections between the paracentral lobule and the brainstem. Lesions to these areas of cortex appear

to directly increase bladder activity by removing cortical inhibitory control (de Groat et al, 1993). Of the brain regions that are initially labeled with PRV from the bladder or urethra, most anatomic, electrophysiologic, and imaging studies to date have implicated the Barrington nucleus as pivotal in regulating bladder function in both animals and man.

Neurotransmitters and Modulators within Brainstem Networks. Knowledge of the neurochemical signals within the central circuits controlling micturition is important for understanding how these circuits function and how they can be manipulated for the treatment of bladder dysfunctions. These were reviewed in detail by Holstege (2005) and by Fowler and colleagues (2008). Much of the current knowledge is based on studies using cats; less is known regarding rats and primates. Glutamate is thought to be the primary neurotransmitter within Barrington nucleus neurons that innervate the preganglionic parasympathetic neurons responsible for detrusor contraction. Both NMDA and non-NMDA receptors have been implicated in this response (Matsumoto et al, 1995a; 1995b; Yoshiyama et al, 1995; Yoshiyama and de Groat, 2005).

Barrington nucleus neurons express corticotropin-releasing factor (CRF) mRNA and protein and a dense CRF terminal field

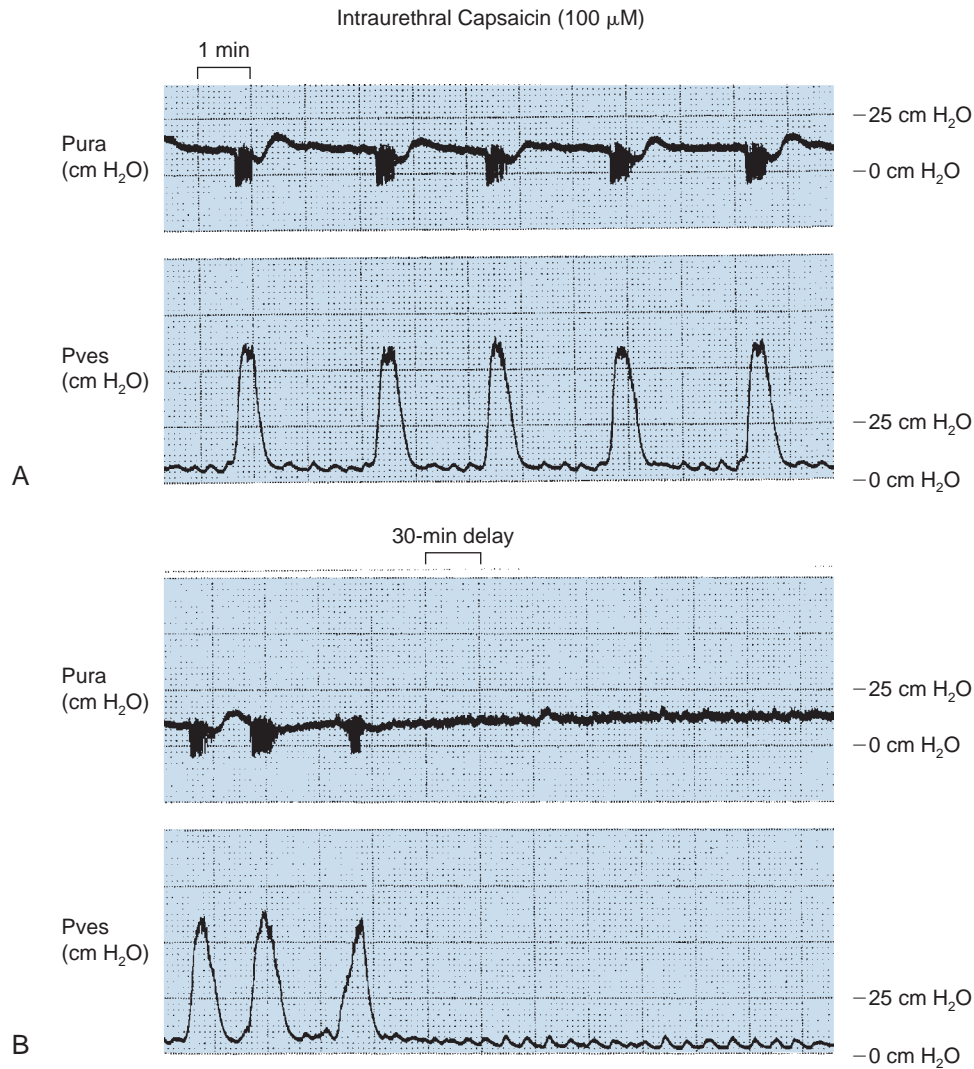

Figure 69-37. Effects of intraurethral capsaicin on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. **A,** Before treatment. **B,** After intraurethral administration of capsaicin (100 μ M). Initially, intraurethral capsaicin instillation increased the bladder contraction frequency, but 30 minutes after continuous infusion, the activity was blocked. (From Jung SY, Fraser MO, Ozawa H, et al. Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. *J Urol* 1999;162:204–12.)

is present in the region of preganglionic parasympathetic neurons of the rat lumbosacral spinal cord (Imaki et al, 1992; Valentino et al, 2000). Recent findings suggest that CRF has an inhibitory influence in this same pathway (Pavcovich and Valentino, 1995). Thus, discrete chemical activation of Barrington nucleus neurons elicits bladder contraction that is enhanced by blocking the CRF influence in the lumbosacral spinal cord with a CRF antagonist. Serotonin appears to affect nervous control of bladder function at multiple levels including sensory processing of bladder wall afferents within the dorsal horn of the spinal cord and at the level of the spinal motoneurons. In all cases this appeared to be an inhibitory influence on detrusor muscle activity but excitatory on urethral sphincter (Burgard et al, 2003). It was proposed that 5-HT_{1A} receptors were located on the terminals of sensory afferent fibers to depress neurotransmitter release.

Human Brain Imaging Studies. In the last decade, the areas of the brain involved in the control of micturition have been examined in human brain imaging studies using single-photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) (DasGupta et al, 2007; Griffiths and Tadic, 2008)

(Fig. 69-39). All these methods provide indirect measures of regional blood flow, assumed to be related to local neuronal activity, but PET is good for measuring long-lasting states of a system, whereas fMRI is better for following relatively fast events. SPECT has rather poor temporal and spatial resolution.

Cerebral Control of Voiding. During human voiding the urethral sphincter relaxes, facilitating urine flow, and the detrusor contracts so as to expel urine. This coordinated relaxation and contraction of urethra and bladder respectively is driven by a long-loop spinobulbospinal reflex (Fowler et al, 2008). As the bladder fills, increasingly strong bladder afferents travel via synapses in the sacral cord to the brainstem and midbrain, where they synapse in the central PAG and possibly Barrington nucleus or PMC. Although there are differing views about how the brainstem circuitry is organized, regardless, if the trigger level is exceeded, efferent signals from the PMC descend to the sacral cord, where they excite an indirect inhibitory pathway via the nucleus of Onuf that leads to sphincter relaxation (Blok and Holstege, 1998) and an excitatory pathway to the bladder that leads to detrusor contraction; thus voiding occurs. Therefore the spinobulbospinal voiding-reflex pathway functions as a switch, either “off” (storage) or “on” (voiding). In the absence of higher control,

Figure 69-38. Schematic depicting information flow among the bladder, spinal cord, and brain. In the rat, spinal cord interneurons relay information about the bladder to the pontine micturition center (PMC), Barrington nucleus, and PAG. The PMC also gets input from the PAG, lateral hypothalamus, and medial preoptic nucleus. PMC neurons project to the locus ceruleus (LC) and preganglionic parasympathetic neurons of the lumbosacral spinal cord that innervate the detrusor. There are also projections to premotor neurons in the dorsal gray commissure that innervate Onuf's nucleus, which projects to the urethral sphincter. A pontine continence center (PCC) has been proposed in the cat and is localized to the L-region of the pons. Neurons here project to the Onuf nucleus.

this switching behavior would lead to involuntary bladder emptying (i.e., incontinence) whenever the bladder volume reached a critical level sufficient to trigger the brainstem switch.

White-matter damage that causes permanent incontinence appears to do so by disrupting a pathway (from medial frontal cortex to brainstem, either direct or via the thalamus) carrying the signal that maintains continence by tonically inhibiting the voiding reflex during storage. Imaging studies using PET (Blok et al, 1997, 1998a; Nour et al, 2000; Athwal et al, 2001; Matsuura et al, 2002) or fMRI (Griffiths et al, 2005; Blok et al, 2006; Di Gangi Herms et al, 2006; Kunze et al, 2006) are in agreement that during bladder filling, storage, and withholding of urine, there is activity in the right inferior frontal or dorsolateral prefrontal cortex, perhaps extending into the lateral part of the superior frontal cortex. There is some right-sided predominance. In contrast, there is little evidence for activation of the medial parts of the frontal cortex during storage. These observations are consistent with the concept that functional imaging reveals gray-matter activation or deactivation, whereas lesions may damage critical links in white-matter connecting pathways also.

Additional Regions. PET scan studies in normal men and women revealed that during voiding two cortical areas (the dorsolateral prefrontal cortex and anterior cingulate gyrus) were active (i.e., exhibited increased blood flow). The hypothalamus, including the preoptic area, as well as the pons and the PAG also showed activity in concert with voluntary micturition (Blok et al, 1997, 1998a).

Another PET study during voiding also confirmed that micturition was associated with increased activity in the pons, inferior frontal gyrus, hypothalamus, and PAG, while also showing activity in several other cortical areas (postcentral gyrus, superior frontal gyrus, thalamus, insula, and globus pallidus) and the cerebellar vermis (Nour et al, 2000).

Many functional imaging studies have observed responses (mostly activations) in ACG to bladder filling, storage, or withholding (Blok et al, 1997, 1998a; Athwal et al, 2001; Matsuura et al, 2002; Griffiths et al, 2005; Yin et al, 2006; Komesu et al, 2011). Response to bladder filling in the dorsal ACG and adjacent supplementary motor area (SMA) is abnormally pronounced in patients with urge incontinence (Griffiths et al, 2007) when, with full bladder but without any actual bladder contraction, they experience the abnormal sensation of urgency (a compelling desire to void that is difficult to inhibit [Abrams et al, 2002], also associated with fear of leakage, i.e., embarrassment) (Abrams et al, 1988). Thus urgency is a powerful homeostatic and social emotion that provides strong motivation to void together with motor output aimed at suppressing incontinence until a socially acceptable location can be reached. fMRI observations in rats confirm activation in the cingulate cortex during bladder filling (Tai et al, 2009), although whether this region is homologous with the human dorsal anterior cingulate cortex (dACC) and whether rats ever experience urgency are not known.

The demonstration by Barrington (1925) in the cat that a center necessary for activation of micturition existed at the level of the

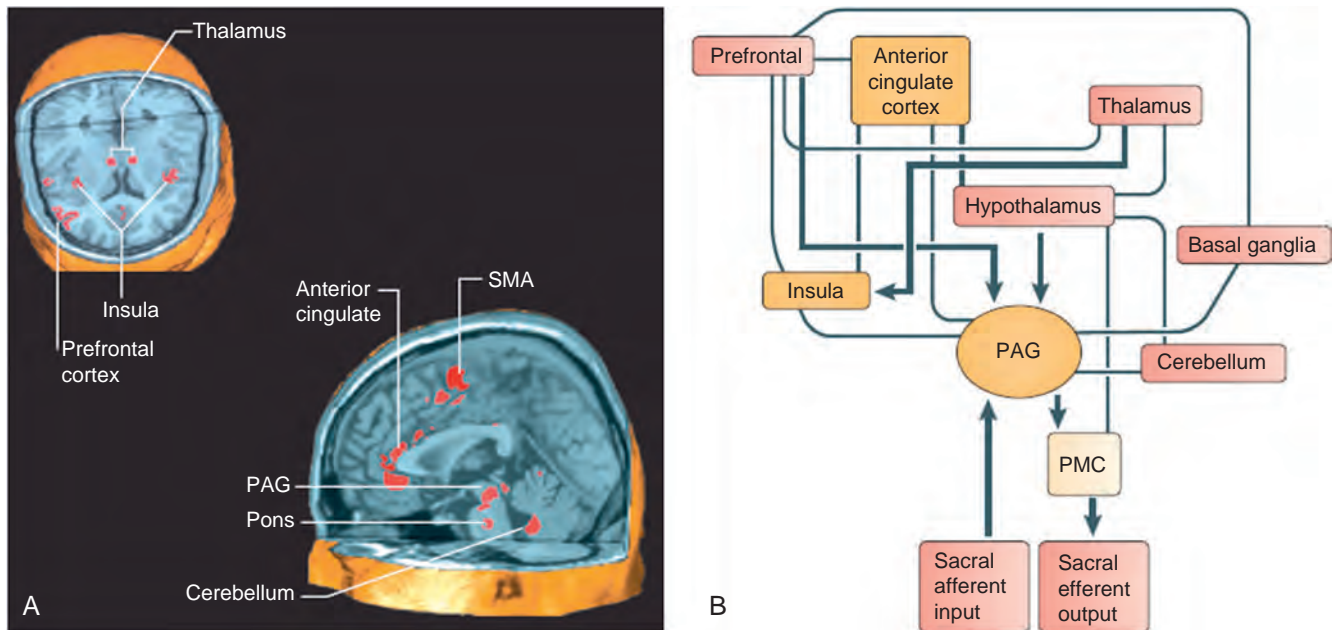

Figure 69-39. Brain areas involved in the regulation of urine storage. **A**, A meta-analysis of positron-emission tomography and functional magnetic resonance imaging studies that investigated which brain areas are involved in the regulation of micturition reveals that the thalamus, the insula, the prefrontal cortex, the anterior cingulate, the periaqueductal gray (PAG), the pons, the medulla, and the supplementary motor area (SMA) are activated during urinary storage. **B**, A preliminary conceptual framework, based on functional brain-imaging studies, suggesting a scheme for the connections among various forebrain and brainstem structures that are involved in the control of the bladder and the sphincter in humans. Arrows show probable directions of connectivity but do not preclude connections in the opposite direction. PMC, pontine micturition center. (From Fowler CJ, Griffiths D, de Groat WC. The neural control of micturition. *Neuroscience* 2008;6:453–66.)

pons provided the background for recognizing a comparable center in humans and the early report of the association of difficulty with micturition with posterior fossa tumors. Later histories of individual cases of discrete pontine lesions (Betts et al, 1992; Manente et al, 1996; Sakakibara et al, 1996; Komiya et al, 1998) and reports of difficulties with micturition or retention as a feature of brainstem gliomas in children (Ueki, 1960; Renier et al, 1980) or vascular lesions (Sakakibara et al, 1996) confirmed the likely existence of a comparable center in humans. Studies using MRI to visualize the precise location of the responsible lesions sited this in the dorsolateral pons, including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and locus ceruleus (Sakakibara et al, 1996). Lesions in this location are frequently associated with disturbances of consciousness and respiration, and bladder symptoms may therefore be overlooked.

Other regions relevant to bladder control and revealed only by functional imaging include parts of parietal and frontoparietal cortices, posterior cortex (precuneus, posterior cingulate cortex), parts of the limbic system (hippocampal complex, amygdala), and the cerebellum. Functional imaging has occasionally shown activity in the basal ganglia, particularly the striatum and putamen (Griffiths et al, 2009). Correspondingly, dopamine pathways are thought to have a profound inhibitory effect on the PMC in health that is lost in Parkinson disease (Winge and Fowler, 2006).

Model of Brain-Bladder Control and Normal Continence Mechanism. The brain regions involved in bladder control are believed to be organized in neural circuits that perform different tasks related to homeostasis, answering questions regarding the adequacy of bladder filling, and the safety and social appropriateness of voiding, as well as the reflex or mechanical aspects dealt with by the brainstem switch. We should therefore expect forebrain control of the switch to involve both limbic circuits (concerned with basic emotion and safety) and cortical circuits (concerned with

social propriety [Amodio and Frith, 2006] and conscious decision making). In the working model, the PAG and PMC form the brainstem switch (Fig. 69-40). The PMC is the final efferent brain nucleus involved in bladder control. The PAG receives numerous projections from forebrain regions (Mantyh, 1982; Mouton and Holstege, 2000) including the medial and orbital prefrontal cortex (An et al, 1998).

During urine storage, as the bladder fills it generates afferent signals that are transmitted to the brainstem switch but do not trigger it. They are relayed from the PAG via the thalamus to the insula (red circuit) and, if activation is strong enough, generate a desire to void. Propagation of this insular activity to the lateral and medial prefrontal cortex enables both a conscious decision about voiding and an assessment of social propriety and possible embarrassment. If no voiding is planned, a return pathway from the medial frontal cortex to the brainstem tonically suppresses the voiding reflex. The pathway may run directly or via the thalamus in the anterior thalamic radiation. The result is postulated to be the normal continence mechanism. When there is a normal sensation of bladder filling, it exerts negative feedback on the brainstem switch, preventing incontinence. Interruption of the negative feedback—for example, by white-matter damage in the medial prefrontal cortex–periaqueductal gray (mPFC–PAG) pathway—leads to incontinence. During normal daily life, however, there is usually no conscious awareness of the bladder at all.

PHARMACOLOGY

Muscarinic Mechanisms

Detrusor strips from normal human bladders are contracted by cholinergic muscarinic receptor agonists and by electric stimulation of intrinsic cholinergic nerves. Contractile responses can be completely abolished by atropine (Sibley, 1984). There are at least five

Figure 69-40. Working model of forebrain control of micturition, showing the brainstem switch and neural circuits that mediate two possible continence mechanisms. The normal mechanism (red) operates when there is a normal sensation of bladder filling. It depends on tonic inhibition of the brainstem switch via a long return pathway from the medial prefrontal cortex to the brainstem switch (probably via the anterior thalamic radiation, but shown for simplicity as a direct connection to the periaqueductal gray [PAG]). The inhibition is switched off for voiding. A backup mechanism (yellow) corresponds to the abnormal sensation or urgency. It may operate via brainstem nuclei such as an L-region (pontine storage center) or by modulating the sympathetic input to bladder and urethra. The dashed blue arrows show a possible circuit concerned with monitoring safety and/or maintaining continence without conscious sensation. dACC, dorsal anterior cingulate cortex; HIP, (para)hippocampal complex (may include amygdala, inferior parts of temporal lobe, and parts of posterior cortex); HYP, hypothalamus; INS, insula; Lat, lateral; L-reg, L-region; med, medial; PAG, periaqueductal grey; PFC, prefrontal cortex; PMC, pontine micturition center; SMA, supplementary motor area; THAL, thalamus.

receptor subtypes based on molecular cloning and four different receptor subtypes based on pharmacology (M_1 to M_5) (Somogyi et al, 1994; Wang et al, 1995; Eglen et al, 1996; Yamaguchi et al, 1996; Hegde et al, 1997).

Pharmacologically, M_1 , M_2 , and M_3 receptor subtypes have been found in the human bladder by receptor binding assays (Kondo et al, 1995); all M_1 to M_5 receptor mRNAs are detected by reverse transcription polymerase chain reaction assays (Andersson and Wein, 2004; Mansfield et al, 2005). Although ligand and receptor binding studies revealed that M_2 receptors predominate, M_3 receptors mediate cholinergic contractions (Eglen et al, 1994; Harriss et al, 1995; Yamaguchi, 1996; Hegde et al, 1997; Lai et al, 1998). Stimulation of M_3 receptors by ACh leads to IP_3 hydrolysis as a result of PLC activation and then to the release of intracellular calcium and smooth muscle contraction (Harriss et al, 1995; Fry et al, 2002) (see Figs. 69-15, 69-17, and 69-18). The involvement of transmembrane flux of calcium ions through nifedipine-sensitive L-type Ca^{2+} channels has also been indicated in M_3 receptor-mediated detrusor muscle contractions because the

L-type Ca^{2+} channel inhibitor nifedipine strongly suppressed carbachol-induced detrusor contractions, whereas the PLC inhibitor or the store-operated Ca^{2+} channel inhibitor caused little inhibition in rats and humans (Andersson and Arner, 2004; Andersson and Wein, 2004; Schneider et al, 2004a, 2004b; Frazier et al, 2008) (see earlier section on calcium signaling in detrusor myocyte). However, other studies have indicated the major contribution of the PLC-mediated mechanism to M_3 receptor-induced detrusor contractions, because PLC inhibitors significantly suppressed carbachol-induced detrusor contractions in rats (Braverman et al, 2006a, 2006b), and intracellular calcium elevation after carbachol application was observed without membrane depolarization in human bladders, which is required for the opening of L-type Ca^{2+} channels (Fry et al, 2002). Hashitani and colleagues (2000) reported that the stimulation of muscarinic receptors activates both calcium influx through L-type Ca^{2+} channels and calcium release from intracellular calcium stores in guinea pig bladders.

It has also been proposed (Hegde et al, 1997; Ehler et al, 2005) that coactivation of M_2 receptors could enhance the response to

M₃ stimulation by (1) inhibition of adenylate cyclase, thereby suppressing sympathetically mediated depression of detrusor muscle; (2) inactivation of K⁺ channels; or (3) activation of non-specific cation channels. In addition, because the specific ROK inhibitor Y-27632 reportedly suppresses carbachol-induced detrusor contractions in rats and humans, muscarinic receptor activation in detrusor smooth muscles is likely to stimulate the ROK pathway, leading to a direct inhibition of myosin phosphatase that induces calcium sensitization to enhance the ability of the muscle to generate the same contractile force with lower levels of intracellular calcium (Andersson and Wein, 2004; Schneider et al, 2004a, 2004b; Frazier et al, 2008). Although the involvement of M₃ receptors for ROK activation has been suggested (Andersson and Arner, 2004; Andersson and Wein, 2004; Schneider et al, 2004a) (see Fig. 69-15), a study has also suggested the participation of M₂ receptors in this mechanism because Y-27632 not only suppressed carbachol-induced muscle contractions but also increased the affinity of darifenacin, an M₃ receptor antagonist with approximately a 30-fold selectivity for M₃ over M₂ receptors, for inhibiting carbachol-induced contractions of rat bladders (Braverman et al, 2006a, 2006b). It has also been reported that the muscarinic receptor subtype-mediated detrusor contractions shift from M₃ to M₂ receptor subtype in certain pathologic conditions, such as obstructed or denervated hypertrophied bladders in rats (Braverman and Rugieri, 2003; Braverman et al, 2006a, 2006b), as well as in bladder

muscle specimens from patients with neurogenic bladder dysfunction (Pontari et al, 2004).

Studies using constructed mutant mice lacking the M₃ receptor or the M₂ and M₃ receptors have demonstrated that this subtype plays key roles in salivary secretion, pupillary constriction, and detrusor contractions (Matsui et al, 2000, 2002; Igawa et al, 2004). However, M₃-mediated signals in digestive and reproductive organs are dispensable, probably because of redundant mechanisms through other muscarinic ACh receptor subtypes or other mediators (Matsui et al, 2000). In addition, it has also been found that male M₃ knockout mice had a distended bladder and larger bladder capacity compared with females, indicating a considerable sex difference in the micturition mechanism (Matsui et al, 2002; Igawa et al, 2004). Thus M₃ or M₂ and M₃ double-knockout mice should provide a useful animal model for the DO pathophysiology and pharmacology.

The muscarinic receptor antagonists tolterodine and oxybutynin (Table 69-4) are widely prescribed drugs for urinary incontinence. Oxybutynin is a nonspecific muscarinic antagonist with additional smooth muscle relaxant properties. The smooth muscle relaxation properties of oxybutynin may be clinically relevant only with intravesical instillation of the drug. In addition, botulinum toxin A injections in children and adolescents diagnosed with neurogenic DO are associated with decreased muscarinic receptor muscular expression (Schulte-Baukloh et al, 2013). Thus, because new

TABLE 69-4 Drugs with Bladder Action

CLASSIFICATION	EXAMPLES	PHARMACOLOGIC ACTION
Anticholinergic agents	Atropine Glycopyrrolate Oxybutynin Propantheline Tolterodine	Inhibit muscarinic receptors, thus reducing the response to cholinergic stimulation; used to reduce pressure during bladder filling and for the treatment of unstable bladder contractions.
Smooth muscle relaxants	Dicyclomine Flavoxate	Direct smooth muscle relaxation reduces intravesical pressure during filling and reduces severity and presence of unstable bladder contractions; most of these agents have some degree of anticholinergic action.
Calcium antagonists	Diltiazem Nifedipine Verapamil	Used in the treatment of unstable bladder contractions to reduce the magnitude of the spikes by reducing the entrance of calcium during an action potential.
Potassium channel openers	Cromakalim Pinacidil	Act to increase the membrane potential and thus reduce the myogenic initiation of unstable bladder contractions.
Prostaglandin synthesis inhibitors	Flurbiprofen	Prostaglandins have been implicated in increased smooth muscle tone and in the induction of spontaneous activity. Inhibition of prostaglandin synthesis could promote relaxation of the bladder during filling and decrease spontaneous activity of the bladder.
β-Adrenergic agonists	Isoproterenol Terbutaline	Stimulation of β receptors induces relaxation of the bladder body, resulting in a decrease in intravesical pressure during filling.
Tricyclic antidepressants	Amitriptyline Imipramine	These agents have anticholinergic, direct smooth muscle relaxant, and norepinephrine reuptake inhibition properties.
α-Adrenergic agonists	Ephedrine Phenylpropanolamine Midodrine Pseudoephedrine	Increase urethral tone and closure pressure by direct stimulation of α-adrenergic receptors.
Afferent nerve inhibitors	DMSO Capsaicin Resiniferatoxin	Reduce the sensory input from bladder and thereby increase bladder capacity and reduce detrusor overactivity.
Estrogen	Estradiol	Direct application to the vagina or oral therapy may increase the thickness of the urothelial mucosa, making a better seal and reducing the incidence of incontinence. Other actions may include increasing adrenergic effects on the urethra and increasing blood flow.

DMSO, dimethyl sulfoxide.

antimuscarinic and other therapies are continually being developed by the pharmaceutical industry, all urologists should be aware of the existence of muscarinic receptor subtypes and their distribution in the LUT and other organs.

We will briefly present two additional issues regarding the effect of antimuscarinic drugs on the bladder and salivary glands that have clinical relevancy. First, antimuscarinic drugs are metabolized, and their metabolites have pharmacologic effects. It has been shown that oxybutynin has less of a dry mouth effect than does its metabolite desethyloxybutynin (Gupta and Sathyan, 1999). Therefore the controlled-release formulation of oxybutynin maintains the efficacy of immediate-release oxybutynin but with significantly fewer side effects. Tolterodine and solifenacin have been shown in cats and rats, respectively, to have less activity on the salivary gland muscarinic receptors than on the bladder muscarinic receptors (Nilvebrant et al, 1997; Ohtake et al, 2004). Second, the site and speed of antimuscarinic metabolism appear to have profound effects in terms of clinical efficacy and side effects.

Muscarinic Selectivity

Pharmacologically defined subtype-selective drugs have been developed. Darifenacin and vamicamide have been demonstrated to be relatively selective for the M_3 subtype (Yamamoto et al, 1995; Andersson, 1997; Steers, 2006). However, they are not necessarily tissue selective, because salivary glands and other tissues also contain M_3 muscarinic receptors. Tolterodine appears to be a muscarinic antagonist that has selectivity for the bladder compared with the salivary gland, even though it may not be an M_3 subtype-selective antagonist (Nilvebrant et al, 1997; Andersson, 1998). More recently, solifenacin has also shown selectivity to the bladder over the salivary gland; the receptor selectivity of solifenacin to M_3 receptors over M_2 receptors (10-fold) is similar to that of oxybutynin (Ikeda et al, 2002; Ohtake et al, 2004). Thus, therapeutically, it is more important to be tissue selective than subtype selective (Nilvebrant et al, 1997; Andersson, 1998). A truly bladder-selective antimuscarinic drug with no side effects is the “Holy Grail” of OAB drug therapy.

In addition, a number of studies have indicated that urothelial cells have the ability to release a variety of neurotransmitters including both ACh and ATP. Both mechanical stimuli and cholinergic agonists can evoke non-neuronal ACh release. Furthermore, stimulating ACh receptors leads to release of ATP, whereas blocking these receptors can reduce this release (Hanna-Mitchell et al, 2007; McLatchie et al, 2014). These and other data suggest that release of ACh can modulate the release of additional transmitters that may help to explain in part the mechanism of action for muscarinic antagonists in reducing symptoms of bladder disorders.

KEY POINTS: MUSCARINIC MECHANISMS

- There are at least five muscarinic receptor subtypes. Pharmacologically, M_1 , M_2 , and M_3 receptor subtypes have been found in the human bladder.
- Stimulation of M_3 receptors by ACh induces calcium influx through L-type Ca^{2+} channels, as well as IP_3 hydrolysis as a result of PLC activation, resulting in the release of intracellular calcium, both of which contribute to a smooth muscle contraction.
- Muscarinic receptor subtype-mediated detrusor contraction shift from M_3 to M_2 receptor subtype has been reported in bladder muscle specimens from neurogenic bladder dysfunction patients.

Adrenergic Mechanisms

β -Adrenergic Receptors

Stimulation of β_2 - and β_3 -adrenergic receptors that exist in the human detrusor results in the direct relaxation of the detrusor

smooth muscle (Andersson, 1993; Morita et al, 1993; Levin and Wein, 1995; Nishimoto et al, 1995). In addition, β -adrenergic-stimulated relaxation is mediated through the stimulation of adenylate cyclase and the accumulation of cAMP (Levin et al, 1986; Andersson, 1993; Andersson and Arner, 2004). Because β -adrenoceptor-mediated relaxation of the human detrusor was not blocked by selective β_1 - or β_2 -adrenoceptor antagonists, such as dobutamine and procaterol, but was blocked by selective β_3 -adrenoceptor antagonists, the relaxation induced by adrenergic stimulation of the human detrusor is mediated mainly through β_3 -adrenoceptor activation (Igawa et al, 1999; Yamaguchi, 2002; Andersson and Arner, 2004). A quantitative analysis by reverse transcription polymerase chain reaction has also confirmed that the β_3 -adrenergic receptor is the most highly expressed subtype among α - and β -adrenoceptor subtypes at the mRNA level in human bladders (Nomiya and Yamaguchi, 2003).

For these and other reasons, the β_3 -receptor agonist mirabegron has been approved as a new treatment option for OAB with symptoms of urge incontinence (Andersson and Arner, 2004; Bridgeman et al, 2013). This agent has been shown to provide an alternative for patients with contraindications or intolerance to existing therapy, although combination therapy (mirabegron and the antimuscarinic solifenacin) has also been shown to be effective (Abrams et al, 2015). The mechanism of action may be related to effects on a number of cell types including bladder afferent activity (Aizawa et al, 2015). Findings in rodents have revealed that β_3 adrenoceptor stimulation with mirabegron increased bladder compliance and shortened the intervoid interval; this regulation may be a result of the effect at a number of sites including reduction of nonmicturition contractions and decreased afferent nerve activation (Sadananda et al, 2013; Aizawa et al, 2015).

A second pharmacologic method of increasing levels of cyclic nucleotide monophosphates (cAMP or cGMP) is use of PDE inhibitors. PDE enzymes catalyze the hydrolysis of cAMP or cGMP (Andersson, 1997; Longhurst et al, 1997; Rahnama'i et al, 2013). There are several classes of PDEs that have individual substrate affinities, specific species and tissue distributions, and pharmacologic selectivities (Truss et al, 1996; Longhurst et al, 1997). Currently, there is considerable research trying to identify the specific isoform of PDE present in the bladder as opposed to that in the penis (Truss et al, 1996). For example, in the isolated guinea pig bladder, the frequency of agonist-induced phasic activity is slowed by cAMP, and degradation of intracellular cAMP in the cells responsible for phasic activity appears to involve primarily PDE4 (Gillespie, 2004). PDE4 inhibitors are shown to suppress DO in a rat model of BOO induced by partial urethral ligation (Kaiho et al, 2008). Although a number of preclinical studies have been done, to date the PDE1 and PDE5 inhibitors have been used clinically for management of storage or voiding disorders.

α -Adrenergic Receptors

Although α -adrenergic stimulation is not prominent in the normal bladder, recent evidence indicates that under pathologic conditions, such as DO associated with BOO, the α -adrenergic receptor density, especially the α_{1D} -receptor subtype, can increase to such an extent that the norepinephrine-induced responses in the bladder are converted from relaxation to contraction (Andersson and Arner, 2004). In rats with outflow obstruction, the proportion of α_{1D} -receptor subtype in the total α_1 -receptor mRNA in the bladder is increased to 70% from 25% in normal rat bladders (Hampel et al, 2002), and urinary frequency is suppressed by an inhibition of α_{1D} and α_{1A} receptors by tamsulosin, whereas α_{1A} -receptor suppression by 5-methyl-urapidil has no effect. Moreover, α_{1D} -receptor knockout mice have larger bladder capacity and voided volumes than do their wild-type controls, which supports an important role of α_{1D} receptors in the control of bladder function (Chen et al, 2005). However, in humans, there is the predominant expression of α_{1D} receptors already in the normal bladder (Malloy et al, 1998), and the level of expression of α -adrenoceptor mRNA, which is considerably low compared with β_3 adrenoceptors in normal bladders, was

not increased in the bladder with outflow obstruction (Nomiya and Yamaguchi, 2003). Thus the contribution of α_{1D} receptors to DO observed in a variety of pathologic conditions, including obstructive uropathy and incontinence, still needs to be established (Andersson and Arner, 2004).

α -Adrenergic mechanisms are more important in urethral function. Substantial pharmacologic and physiologic evidence indicates that urethral tone and intraurethral pressure are influenced by α -adrenergic receptors. The presence of α_1 and α_2 adrenoceptors has been shown in the urethra of various species including humans. Among α_1 adrenoceptors, the α_{1A} adrenoceptor is the major subtype expressed in urethral smooth muscle at the mRNA and protein levels (Yono et al, 2004; Michel and Vrydag, 2006). Isolated human urethral smooth muscle contracts in response to α -adrenergic agonists (Yalla et al, 1977; Awad et al, 1978; Nordling, 1983; Mattiasson et al, 1984). It is also reported in the rabbit that the urethral contraction is mediated by the α_{1A} -adrenoceptor subtype (Testa et al, 1993; Michel and Vrydag, 2006). Likewise, hypogastric nerve stimulation and α -adrenergic agonists raise intraurethral pressure, which is blocked by α_1 -adrenergic antagonists (Awad et al, 1976; Yalla et al, 1977). These findings provide the rationale for use of α -adrenergic agonists to promote urine storage by increasing urethral resistance.

Conversely, α -adrenergic receptor antagonists facilitate urine release in conditions of functionally increased urethral resistance, such as benign prostatic hyperplasia (BPH). Although the α_{1A} adrenoceptor is the major subtype in the prostate and urethra, highly selective α_{1A} -adrenoceptor antagonists (e.g., RS-17053) do not alter LUTS scores in men with BPH, but these agents are effective at relaxing prostate smooth muscle and increasing urine flow in men (Schwinn and Roehrborn, 2008). In contrast, α_1 -adrenoceptor antagonists that contain α_{1D} -adrenoceptor blocking activity improve bladder-based symptoms in humans (Nishino et al, 2006), suggesting the important role of the α_{1D} -adrenoceptors for storage symptoms associated with BOO, receptors potentially located at the bladder or the spinal cord (Schwinn and Roehrborn, 2008).

α_2 -Adrenergic antagonists increase the release of norepinephrine from urethral tissues through a presynaptic mechanism, but this does not affect the contractility of urethral smooth muscle in vitro (Mattiasson et al, 1984; Willette et al, 1990; Michel and Vrydag, 2006). The human urethra lacks postjunctional α_2 -adrenergic receptors, although in vitro prejunctional activation of these receptors produces a feedback inhibition of norepinephrine release. Pharmacologic and electrophysiologic data suggest that adrenergic nerves influence excitatory cholinergic transmission in pelvic ganglia. de Groat and Booth (1993) have shown in the cat that hypogastric nerves inhibit excitatory cholinergic transmission in vesical ganglia by activation of α_2 -adrenergic receptors (Fig. 69-41). Conversely, β -adrenergic agonists facilitate transmission in vesical ganglia.

KEY POINTS: ADRENERGIC MECHANISMS

- β -Adrenergic-stimulated relaxation is mediated through the activation of adenylate cyclase and the accumulation of cAMP.
- The β_3 -adrenergic receptor is the most highly expressed subtype among α - and β -adrenoceptor subtypes, and β_3 -receptor agonists are in clinical trials for treatment of DO.
- In the human, there is a predominant expression of α_{1D} receptors present in the normal bladder, and the level of expression of α -adrenoceptor mRNA, which is considerably low compared with β_3 adrenoceptors in normal bladders, was not increased in the bladder with outflow obstruction.
- Urethral tone and intraurethral pressure are influenced by α -adrenergic receptors. The α_{1A} adrenoceptor is the major subtype in the prostate and urethra, and all three α_1 -adrenoceptor subtypes (α_{1A} , α_{1B} , α_{1D}) are present in blood vessels.

Figure 69-41. Diagram of possible transmitters in an adrenergic terminal supplying the bladder or urethra. Norepinephrine (NE) release can activate α_1 -adrenergic receptors and produce contraction (+) or β receptors and cause relaxation (-) of the detrusor. Feedback inhibition of NE release through α_2 receptors can also occur. Neuropeptide Y (NPY) can produce smooth muscle contraction (+) or inhibit acetylcholine (ACh) release (not shown), or feedback can inhibit NE release. Adenosine triphosphate (ATP) can activate P_2 receptors in the detrusor, which elicit contraction (+) or inhibit (-) further ATP release through P_1 prejunctional receptors. ACh release from terminals in synaptic contact with an adrenergic varicosity can inhibit firing of adrenergic axons by activation of M_1 receptors.

Urethral Tone in Women

Taki and associates (1999) separated the entire length of the human female urethra into several parts and studied the regional contractile effect of norepinephrine, clonidine, ACh, and potassium chloride. Their findings suggest that sympathetic innervation helps maintain resting urethral tonus, mainly through α_1 adrenoceptors. With the recent identification of at least three distinct subtypes of α_1 adrenoceptors with distinct pharmacologic profiles, it may be possible to develop urethra-specific pharmacologic agonists for the treatment of stress urinary incontinence (SUI). A small-scale, placebo-controlled clinical study has demonstrated that activation of the $\alpha_{1A/1L}$ -adrenoceptor subtype, which is a pharmacologic isoform of the α_{1A} -adrenoceptor gene product, was effective in reducing the number of incontinence episodes in women with mild-to-moderate SUI (Musselman et al, 2004), suggesting an important role of α_1 adrenoceptors in the urethral continence mechanism, although the data are still preliminary.

Afferent Neuropeptides

Afferent neurons innervating the LUT exhibit immunoreactivity for various neuropeptides, such as SP, CGRP, pituitary adenylate cyclase-activating polypeptide (PACAP), leucine enkephalin, CRP, and VIP (de Groat, 1986, 1989; Keast and de Groat, 1992; Maggi, 1993; Vizzard, 2001, 2006), as well as growth-associated protein-43 (GAP43), NOS (Vizzard et al, 1996), glutamic acid, and aspartic acid (Keast and Stephensen, 2000). These substances have been identified in many species and at one or more locations in the afferent pathways including (1) afferent neurons in lumbosacral DRG, (2) afferent nerves in the peripheral organs, and (3) afferent

axons and terminals in the lumbosacral spinal cord (Kawatani et al, 1985, 1986, 1996; Morrison et al, 2005). The majority (>70%) of bladder DRG neurons in rats appear to contain multiple neuropeptides—CGRP, SP, and PACAP being the most common. In cats, VIP is also contained in a large percentage of bladder DRG neurons (de Groat, 1989).

Many of these peptides, which are contained in capsaicin-sensitive, C-fiber bladder afferents, are released in the bladder by noxious stimulation and contribute to inflammatory responses by triggering plasma extravasation, vasodilation, and alterations in bladder smooth muscle activity (Maggi, 1993; Ishizuka et al, 1994, 1995). These agents also function as transmitters at afferent terminals in the spinal cord.

Tachykinins

The tachykinins are a family of small peptides sharing a common C-terminal sequence, Phe-Xaa-Gly-Leu-Met-NH₂, whose main members are SP, neurokinin A, and neurokinin B. Tachykinins are found in both central and peripheral nervous systems. In the peripheral nerves, tachykinins are predominantly located in the terminals of nonmyelinated, sensory C fibers. The diverse biologic effects of the tachykinins are mediated through three receptors, designated NK₁, NK₂, and NK₃, which belong to the superfamily of seven transmembrane-spanning G protein-coupled receptors (Khawaja and Rogers, 1996). SP is the most potent tachykinin for the NK₁ receptor, whereas neurokinin A exhibits the highest affinity for the tachykinin NK₂ receptor, and neurokinin B for the tachykinin NK₃ receptor (Table 69-5). All receptor subtypes have been identified in the bladder of humans and animals such as rats, mice, and dogs (Lecci and Maggi, 2001; Andersson and Arner, 2004).

Tachykinins released from capsaicin-sensitive sensory C fibers in response to irritation in the bladder can act on (1) NK₁ receptors in blood vessels to induce plasma extravasation and vasodilation, (2) NK₂ receptors to stimulate bladder contractions, and (3) NK₃ receptors on primary afferent terminals to increase the excitability during bladder filling or during bladder inflammation (de Groat, 1989; Andersson, 1993; Morrison et al, 1995; Lecci and Maggi, 2001). A study by Kamo and associates (2005) also demonstrated that activation of NK₃ receptors on capsaicin-sensitive C-fiber afferents in the rat bladder can increase the excitability during bladder filling.

Intrathecal administration of NK₁ antagonists (RP 67580 and CP 96345) or systemic application of centrally acting NK₁ antagonists (GR 205171 and CP 99994) increased bladder capacity in normal rats and guinea pigs, respectively, without changing voiding pressure, whereas NK₂, NK₃, or peripherally acting NK₁ antagonists were ineffective (Lecci et al, 1993; Yamamoto et al, 2003). DO in rats induced by chemical cystitis, intravesical administration of capsaicin, or intravenous injection of L-dopa was also suppressed by intrathecal injection of NK₁ antagonists (Ishizuka et al, 1994; Lecci et al, 1994; Ishizuka et al, 1995). DO induced by capsaicin was reduced by an NK₂ antagonist (SR 48965) that did not influence normal voiding (Lecci et al, 1997). In anesthetized guinea pigs, TAK-637, an NK₁ receptor antagonist, administered orally or intravenously also increased the volume threshold for inducing micturition and inhibited the micturition reflex induced by capsaicin applied topically to the bladder (Doi et al, 1999). In a clinical study, an NK₁ receptor antagonist, aprepitant, has also been shown to effectively decrease the average daily number of micturitions and urgency episodes compared with placebo at 8 weeks in women with

idiopathic OAB (Green et al, 2006). These results indicate that sensory input to the spinal cord from non-nociceptive bladder afferents is mediated by tachykinins acting on NK₁ receptors, whereas input from nociceptive afferents in the bladder can be mediated by NK₁, NK₂, and NK₃ receptors. In addition, tachykinin NK₃ receptor activation in the spinal cord can inhibit the micturition reflex through an activation of the spinal opioid mechanism (Kamo et al, 2005).

Autofeedback mechanisms may also be important at afferent nerve terminals. As mentioned earlier, some stimuli are known to release neuropeptides from afferent nerves, and these neuropeptides may, in turn, sensitize the afferents. NK₂ agonists were found (Wen and Morrison, 1996) to sensitize bladder mechanoreceptors by acting on NK₂ autoreceptors in the sensory endings in the bladder mucosa to produce the combination of effects found previously for other sensitizing agents (Morrison et al, 1998). The NK₂ receptor blocker SR 48968 decreases the sensitivity of bladder mechanoreceptors and also blocks the sensitization produced by NK₂ agonists and high urinary potassium levels. This suggests that the sensitization produced by intravesical chemical stimuli may be caused by a mechanism using the NK₂ receptor. On the basis of these findings, it could be hypothesized that high urinary potassium concentration or higher levels of bladder distention release neurokinin A from sensory endings, and that the sensitization is the result of the action of the peptide on local NK₂ autoreceptors on the sensory endings. It has also been shown that sensory neurons obtained from rat DRG can be excited by NK₂ agonists and inhibited by NK₃ agonists through modulation of Ca²⁺ channel activity mediated by PKC activation (Sculptoreanu and de Groat, 2003). NK₂ receptor activation also leads to PKC-induced phosphorylation of TRPV1 channels, resulting in an increase in capsaicin-evoked currents in rat DRG neurons (Sculptoreanu and de Groat, 2007; Sculptoreanu et al, 2008).

Prostanoids

Prostanoids (prostaglandins and thromboxanes), which comprise a family of oxygenated metabolites of arachidonic acid, by the enzymatic activity of cyclooxygenases 1 and 2, are manufactured throughout the LUT and have been implicated in bladder contractility, inflammatory responses, and neurotransmission. Biopsy specimens of human bladder mucosa contain PGI₂, PGE₂, PGE_{2w}, and thromboxane A. In decreasing order of potency, PGF_{2w}, PGE₂, and PGE₂ contract the human detrusor (Andersson, 1993; Andersson and Arner, 2004). The actions of prostanoids are mediated by specific receptors on cell membranes. The receptors include the DP, EP, FP, IP, and TP receptors that preferentially respond to PGD₂, PGE₂, PGF_{2w}, PGI₂, and thromboxane A₂, respectively. Furthermore, EP is subdivided into four subtypes: EP₁, EP₂, EP₃, and EP₄ (Breyer et al, 2001, 2003). The slow onset of action for these substances suggests a modulatory role for prostaglandins. Some prostaglandins may affect neural release of transmitters, whereas others inhibit acetylcholinesterase activity. These actions provide mechanisms whereby prostaglandins could potentially augment the amplitude of cholinergic-induced detrusor contractions (Borda et al, 1982).

Attempts to use prostaglandins to facilitate voiding have had mixed results. Intravesical PGE₂ has been shown to enhance bladder emptying in women with urinary retention and patients with neurogenic voiding dysfunction (Bultitude et al, 1976; Vadyanaathan et al, 1981; Tammela et al, 1987). Others have failed to find PGE₂ useful to facilitate complete evacuation of the bladder (Delaere et al, 1981; Wagner et al, 1985). Intravesical PGE₂ does produce urgency and involuntary bladder contractions (Schussler, 1990). Consistent with this finding, inhibition of prostaglandin synthesis with indomethacin reduces DO (Cardozo and Stanton, 1980).

Endothelins

Endothelins (ETs), a family of 21-amino acid peptides (originally isolated from bovine aortic endothelial cells), include ET-1, ET-2, and ET-3, which are encoded by separate genes and mediate a

TABLE 69-5 Tachykinins and Tachykinin Receptors

TACHYKININ	RECEPTOR
Substance P	NK ₁
Neurokinin A	NK ₂
Neurokinin B	NK ₃

variety of biologic actions through two distinct G protein-coupled receptor subtypes, the endothelin-A (ET_A) and the endothelin-B (ET_B) receptor (Yanagisawa et al, 1988; Masaki, 2004). The ET_A receptor subtype has a higher affinity for ET-1 and ET-2 than for ET-3; the ET_B receptor subtype binds all ETs with equal affinity (Rubanyi and Polokoff, 1994). ET-1, which is known to be primarily produced by human endothelial cells, can induce prolonged contractile responses in isolated urinary bladder muscle strips in various species (Maggi et al, 1990; Khan et al, 1999). In humans and rabbits, ET-like immunoreactivity is identified in almost all cell types in the bladder, including bladder epithelium, vascular endothelium, detrusor, and vascular smooth muscles, and fibroblasts; it plays a role in control of bladder smooth muscle tone, regulation of local blood flow, and bladder wall remodeling in pathologic conditions (Saenz de Tejada et al, 1992). In a rabbit model of BOO, ET-1 and ET_A receptor binding sites in detrusor smooth muscle and urothelium, as well as ET_B receptor binding sites in detrusor smooth muscle, were significantly increased (Khan et al, 1999). In addition, the ET-converting enzyme inhibitor WO-03028719, which suppresses ET-1 production, can improve voiding efficiency and suppress DO in a rat model of BOO (Schroder et al, 2004). YM598, a selective ET_A receptor antagonist, also reduces DO in urethral obstructed rats (Ukai et al, 2006). These results suggest that the increase in ET-1 expression and ET receptors could be involved in detrusor hyperplasia and overactivity seen in patients with BOO resulting from BPH.

There is also evidence that ETs have a role in modulation of sensory function in the peripheral nervous system and CNS. The activation of ET_A receptors in capsaicin-sensitive C-fiber afferents in the bladder induces DO, whereas ET_A receptor activation in the spinal cord can inhibit the micturition reflex through activation of a spinal opioid mechanism in rats (Ogawa et al, 2004). In spinal cord-injured rats, the bladder ET-1 level was increased, and the application of ABT-627, an ET_A antagonist, suppressed C fiber-mediated DO. Accordingly, modulation of ET_A receptor activity in bladder afferent pathways or the spinal cord could be effective in treating bladder overactivity or painful conditions (Ogawa et al, 2008).

Sex Steroids

Differences in responses of human and animal bladders to the effect of drugs suggest that sex steroids play a role in detrusor contractility. It is not unusual for women to note changes in voiding, bladder pain, or continence at different times of their menstrual cycle. Sex steroids do not directly affect bladder contractility, but they modulate receptors and influence growth of bladder tissues. Estrogen receptors are expressed by the trigone in women (Iosif et al, 1981). Levin and associates (1980) noted that bladder body muscle from young female rabbits treated with estrogens exhibits increased responsiveness to α -adrenergic, cholinergic, and purinergic agonists. Others have seen a decreased density of adrenergic and muscarinic receptors in the bladder after estrogen administration (Shapiro, 1986; Batra and Andersson, 1989). In contrast to the study by Levin and coworkers (1980), Elliott and associates (1992) showed that bladder smooth muscle from estrogen-treated rats exhibited decreased contractions.

Estrogens also increase adrenergic receptors in the urethra (Calahan and Creed, 1985). Ekstrom and associates (1993) reported that estrogen administration to ovariectomized rabbits unmasked contractile responses to α -adrenergic agonists, whereas contracted and normal rabbit bladders demonstrated no response to these agents. Some clinicians have combined these agents to elevate urethral pressure in patients with stress incontinence (Wilson et al, 1987). However, the clinical efficacy of the combined use of estrogen with α agonists has been questioned (Walter et al, 1978). The effect of estrogens on urinary continence in females probably reflects the multiple actions of this hormone on adrenergic receptors, vasculature, and urothelium. In addition, progesterone increases electrical and cholinergic contractions of the bladder. Exogenous estrogens and progesterones also induce NOS

activity in bladders of female guinea pigs (Ehren et al, 1995). This effect is postulated to contribute to relief of DO with hormonal treatment. However, the use of estrogens alone to treat either SUI or urgency incontinence has given disappointing results (Abrams et al, 2005), and studies have suggested that estrogen may be associated with an increase in urinary incontinence in postmenopausal women (Hendrix et al, 2005).

Androgen treatment in the male rat has been reported to have similar effects on synaptic connections, as well as effects on motoneuronal somatic and dendritic size in the androgen-sensitive motoneurons innervating the bulbocavernosus and levator ani muscles of the rat (Jordan, 1997; Matsumoto, 1997). Testosterone treatment can also influence the size of postganglionic neurons in the major pelvic ganglion of the male rat (Keast and Saunders, 1998). Thus further studies are needed to evaluate the influence of changes in hormonal environment on the neural pathways controlling the LUT.

CLINICAL RELEVANCE

The following section discusses different LUTD conditions encountered by urologists that involve perturbation of the physiologic mechanisms presented in this chapter. Some of these conditions arise as a result of injuries to innervation, obstruction, or infection of the LUT. On a logical level, the ideal treatment for these conditions would be to reverse the neurologic injury, relieve the obstruction, or eradicate the infection. When LUTD, manifesting with LUTS, increased postvoid residual volume, and/or DO, has no identifiable pathology, then the treatment becomes empirical and driven primarily by LUTS relief. A variety of diagnostic terms have been used to describe idiopathic LUTD conditions—OAB, IC/PBS, and underactive bladder to name a few. Many of these idiopathic LUTD conditions reflect an increased or augmented sensory input from the LUT, leading to the term *afferent neurolurology* in describing these conditions (Clemens, 2013). Although idiopathic nonobstructive urinary retention (underactive detrusor) may be primarily a failure of efferent signaling, the resultant decreased motor sensory pathway (Eastham and Gillespie, 2013) could exacerbate or prolong this condition. The ability to augment or inhibit sensory afferent mechanisms in treating these afferent neurolurologic conditions could advance treatment for LUTD.

One overarching paradigm to explain afferent neurolurologic conditions involves C-fiber afferent activation via neurotrophic cytokine, such as nerve growth factor (NGF), signaling. Changes in bladder innervation orchestrated by neurotrophins manufactured by detrusor smooth muscle are temporally linked with DO (Fig. 69-42). The ability of local anesthetics, intravesical afferent neurotoxins, and destruction of afferent nerves in the bladder neck and prostate to reduce urgency, frequency, and urgency incontinence indicates an important role for afferent-evoked reflexes (Chalfin and Bradley, 1982). The development of a spinal reflex (ice-water test response) in patients with neurogenic bladders (Geirsson et al, 1999), as well as in patients with BOO (Chai et al, 1998; Hirayama et al, 2003, 2005), suggests a common underlying plasticity in nerves supplying the bladder. Moreover, the association between elevated blood pressure and LUTS in patients with BPH (Pool, 1994; Sugaya et al, 2003) provides a link between changes in sympathetic tone and voiding complaints.

Mechanisms of Idiopathic Detrusor Overactivity and Overactive Bladder

The classic model of OAB is that of urodynamically demonstrated DO, although DO was found in only 11% of a contemporary cohort of subjects with OAB symptoms (Diamond et al, 2012). Nevertheless, various models have been used to explore the pathogenesis of DO and to formulate treatments for urgency incontinence associated with OAB. Animal models for DO that do not involve damage or injury to bladder, urethra, or spinal cord include

Figure 69-42. Possible mechanisms underlying plasticity in bladder reflex pathways induced by various pathologic conditions. Bladders from rats with chronic spinal cord injury, urethral obstruction, chronic inflammation, and bladder denervation and those that are spontaneously hypertensive exhibit increased level of neurotrophic factors (NTFs), such as nerve growth factor. NTFs can increase the excitability of C-fiber bladder afferent neurons and alter reflex mechanisms in parasympathetic excitatory pathways in the pelvic nerve (PN), as well as in sympathetic pathways in the hypogastric nerve (HGN). These reflex circuits are organized in the spinal cord as positive-feedback loops that induce involuntary bladder activity. In certain situations, such as the spontaneously hypertensive rat, peripheral efferent mechanisms are also altered: Excitatory α_1 -adrenoceptor mechanisms are upregulated, providing an additional excitatory input to the bladder.

the spontaneously hypertensive rat (Steers et al, 1999), serotonin reuptake transporter knockout (Cornelissen et al, 2005), constitutive BK channel knockout (Meredith et al, 2004), urothelially restricted NGF knock-in (Schnegelsberg et al, 2010), and urothelially restricted β_1 -integrin knockout (Kanasaki et al, 2013). Other molecular targets, using transgenic animals, have been used to study LUT function, although none of these models has specifically addressed the clinical problem of DO or OAB. These animal models include knockout mice lacking muscarinic receptors (M_1 to M_5) (Matsui et al, 2002; Igawa et al, 2004), purinergic receptors ($P2X_2$, $P2X_3$) (Cockayne et al, 2000, 2005), and TRPV1 (Birder et al, 2002). With some of these models, a mechanistic theme is alterations in growth factors leading to plasticity in micturitional neural and smooth muscle contractile pathways.

NGF has been a biomarker for LUTD since the description of NGF upregulation by bladder smooth muscle after BOO and increased diuresis (Steers et al, 1991; Steers and Tuttle, 2006). The role of increased urinary NGF as a biomarker for OAB has been studied (Liu et al, 2009, 2011; Liu and Kuo, 2012; Seth et al, 2013). Although the source of the urinary NGF is uncertain, it is less likely to come from the bladder stroma because of the necessity of NGF having to traverse the lamina propria and the entire urothelium. However, the role of increased NGF expressed by the bladder urothelium in mediating a change in bladder function was studied in transgenic mice with overexpression of NGF restricted to the urothelium (Schnegelsberg et al, 2010). These animals had increased urinary frequency, pelvic pain, and prominent neuronal hypertrophy in the lamina propria. Investigators failed to detect increased urothelial tissue NGF in DO subjects and paradoxically less urothelial tissue NGF in subjects with increased urinary frequency (Birder et al, 2007b). It remains to be seen how NGF can be used in evaluation, phenotyping, and/or treatment of OAB, and further studies are needed (Ochodnick et al, 2011).

Urothelial dysfunction associated with idiopathic OAB has also been studied using human urothelial cells grown in culture. The findings from using human cells in these *in vitro* studies included increased urothelial polyamine signaling (Li et al, 2013) leading to block of urothelial BK channels (Li et al, 2009). Other findings

include increased TRPV1 signaling in the cultured OAB cells (Li et al, 2011). Whether these urothelial abnormalities related to altered bladder urothelial-afferent signaling remains to be seen.

Investigators found that subjects with OAB and urgency incontinence had decreased urethral afferent function (Kenton et al, 2007, 2010) when measured with urethral CPT (current perception threshold) testing. Furthermore, 2 weeks after successful sacral neuromodulation treatment, urethral CPT measures did not change (Gleason et al, 2013). These findings are counterintuitive because one would expect augmented urethral afferent function in OAB. An animal model in which urethral afferent signaling can be selectively modulated (augmented or diminished) would help shed light on the impact of urethral afferent signaling on micturitional behavior.

The role of bladder smooth muscle pathophysiology in OAB and DO has also been studied. In the constitutive BK knockout mouse, development of OAB micturitional behavior phenotype was seen (Meredith et al, 2004). The ability to obtain detrusor smooth muscle strips in idiopathic urgency incontinence patients is limited, so confirmation of this phenomenon would be difficult, unlike the case of neurogenic DO (see next section). Other investigators have examined derangements in regulation of (Ca^{2+})_i from detrusor myocytes isolated from both idiopathic and neurogenic DO subjects (Sui et al, 2009). These investigators found that myocytes from DO had increased resting (Ca^{2+})_i, and more spontaneous increases in (Ca^{2+})_i arising from influx of extracellular Ca^{2+} from L-type and T-type VDCCs. There was a suggestion that neurogenic DO had greater dysregulation of (Ca^{2+})_i than IDO.

The role of suburothelial myofibroblasts has been also explored in OAB. Immunofluorescent studies of these myofibroblasts from both idiopathic and neurogenic DO subjects revealed increased gap junction (Cx43) expression in the myofibroblasts (Roosen et al, 2009). Furthermore, these changes were not reversed, even with successful treatment with onabotulinumtoxinA (OBTX). The links among myofibroblasts; detrusor myocytes; cytokines including interleukin-4 (IL-4), IL-6, IL-10; tumor necrosis factor- α (TNF- α); and transforming growth factor- β 1 (TGF- β 1); and Cx43 were investigated (Heinrich et al, 2011). These investigators found that these

cytokines increased expression of Cx43 in both myofibroblasts and myocytes, suggesting a mechanism for increased cellular connectivity in OAB (and IC/PBS) that is related to these cytokines. Although NGF was not tested in this study, investigators using PC12 cells (neuronal cells) found that NGF increased Cx43 connectivity in these cells (Cushing et al, 2005), which suggests that NGF could possibly also increase Cx43 expression in detrusor myocytes and myofibroblasts.

Stress Urinary Incontinence

Traditionally, SUI in women has been thought to be a urethral anatomic and not a urethral physiologic problem. The urethral integral theory of Petros and Ulmsten (1993) led to the development of the mid-urethral sling, the current standard surgical treatment for SUI. However, SUI in women is unlikely to be caused only by anatomic laxity of the anterior vaginal wall. DeLancey presented data that showed intrinsic sphincteric function (physiologic function) to be more important for maintenance of stress continence than anatomic integrity (anatomic support) (DeLancey, 2010). Pathophysiologic studies of urethral function in women have centered on the mechanisms surrounding urethral injury at time of childbirth using vaginal distention animal models, including pudendal nerve injuries (Damaser et al, 2007; Pan et al, 2009). Chemokines and receptors involved in stem cell homing, such as CCL7, CXCR4, CXCL12, CD195, and CD193 were upregulated with vaginal distention or after vaginal birth in rats (Lenis et al, 2013). Increased expression of monocyte chemoattractant protein-3 (MCP-3) at the urethra after vaginal distention provides a homing signal for stem cells, because MCP-3 is a stem cell homing chemokine (Woo et al, 2007). A possible method to diminish SUI after childbirth is to maximize healing of urethral injuries (both muscular and neurologic) soon after childbirth.

The ability to use biomarkers to predict success or failure after mid-urethral slings was studied (Chai et al, 2014). This study found that higher urinary NTx (N-telopeptide cross-linked collagen) was associated with a significantly higher failure rate after slings. NTx is a marker for bone metabolism; higher NTx levels reflect greater bone turnover and osteoporosis (Garnero, 2008). It remains to be seen whether leveraging this knowledge can reduce the failure rate of mid-urethral slings, which at 1 year is about 23% (Richter et al, 2010).

Serotonin-norepinephrine reuptake inhibitors, such as duloxetine, increase efferent output at the Onuf nucleus at the sacral spinal cord, thus increasing urethral smooth muscle tone and decreasing SUI (Thor and Katofiasc, 1995). Clinical trials of duloxetine have shown benefits over placebo in treating mild-to-moderate SUI (Millard et al, 2004; van Kerrebroeck et al, 2004). Duloxetine is approved in Europe, but not the United States, for use in SUI. Duloxetine has also been studied in male postprostatectomy SUI and was found to have statistically significant efficacy over placebo, although the sample size was small (Cornu et al, 2011).

Spinal Cord Injury and Neurogenic Detrusor Overactivity

Damage to the spinal cord above the sacral spinal level results in DO (Kaplan et al, 1991; Chancellor, 1997). Acute spinal cord injury disrupts normal supraspinal circuits that control urine storage and release. After the spinal shock period of urinary retention that typically lasts a few weeks, neurogenic DO develops. Electrophysiologic data reveal that this DO is mediated by a spinal micturition reflex that emerges in response to a reorganization of synaptic connections in the spinal cord (de Groat, 1975; de Groat et al, 1981, 1990; Araki and de Groat, 1997; Yoshimura, 1999). In addition, bladder afferents that are normally unresponsive to low intravesical pressures become more mechanosensitive, leading to the development of DO.

Normal micturition is associated with a spinobulbospinal reflex mediated by lightly myelinated A δ afferents (de Groat et al, 1975, 1993). These fibers represent only 30% of bladder afferents in some species. Compared with A δ fibers, the more prevalent

unmyelinated C fibers are relatively insensitive to gradual distention of the urinary bladder, at least in the cat (Häbler et al, 1990). Most C fibers in this species remain silent during normal filling of the bladder, although in the rat, some studies indicate that C fibers can fire at low pressures (Sengupta and Gebhart, 1994), whereas other studies (Morrison, 1998) showed firing at higher intravesical pressures of approximately 30 mm Hg. After spinal cord injury, a capsaicin-sensitive C fiber-mediated spinal reflex develops (see Fig. 69-25). These C-fiber afferents are thought to play a role in the development of DO after spinal cord injury. Capsaicin-sensitive C fibers have also been implicated in DO after upper motoneuron diseases, such as spinal cord injury and multiple sclerosis (Fowler et al, 1992, 1994; Geirsson et al, 1995; Szallasi and Fowler, 2002). Studies in multiple sclerosis and spinal cord-injured patients with DO also revealed an increased density of TRPV1 and P2X₃ immunoreactivity in suburothelial nerves and increased TRPV1 immunoreactivity in the basal layer of the urothelium (Brady et al, 2004; Apostolidis et al, 2005b). Treatment of these patients with intravesical capsaicin or another C-fiber neurotoxin, RTX, reversed these abnormalities (Brady et al, 2004).

Insight into the mechanisms underlying the increased mechanosensitivity of C fibers after spinal cord injury has been gained by examination of the DRG cells innervating the bladder. Plasticity of these afferents manifests with enlargement of these DRG cells (Kruse et al, 1995) and increased electrical excitability (Yoshimura and de Groat, 1997; Yoshimura, 1999). Upregulation of tetrodotoxin (TTX)-sensitive Na⁺ channels and downregulation of TTX-resistant Na⁺ channels, as well as low-threshold A-type K⁺ channels, occur after spinal cord injury (Yoshimura and de Groat, 1997; Yoshimura, 1999).

Plasticity in bladder afferents after spinal cord injury and upper motoneuron lesions may involve the retrograde transport of substances from either the spinal cord or the bladder to the DRG neuron. NGF has been implicated as a chemical mediator of disease-induced changes in C-fiber afferent nerve excitability and reflex bladder activity (Yoshimura, 1999; Vizzard, 2000). Chronic administration of NGF into bladder afferent pathways induced bladder overactivity and increased the firing frequency of dissociated bladder afferent neurons in rats (Yoshimura et al, 2006), and the production of neurotrophic factors, including NGF, increased in the bladder after spinal cord injury (Vizzard, 2000). Thus it seems that target organ-neural interactions mediated by neurotrophic factors, such as NGF, produced in the bladder may contribute to changes in C-fiber bladder afferent pathways that induce DO and detrusor-sphincter dyssynergia after spinal cord injury. In addition, increased NGF in the spinal cord after spinal cord injury is also responsible for inducing hyperexcitability of C-fiber bladder afferent pathways, and intrathecal application of NGF antibodies, which neutralizes NGF in the lumbosacral spinal cord and DRG, suppresses DO and detrusor-sphincter dyssynergia in spinal cord-injured rats (Seki et al, 2002). Intrathecal administration of NGF antibodies also blocks autonomic dysreflexia in paraplegic rats (Krenz et al, 1999). Thus NGF and its receptors in the bladder or the spinal cord are potential targets for new therapies to suppress DO and detrusor-sphincter dyssynergia after spinal cord injury.

Other neurogenic disorders associated with urgency incontinence respond to intravesical therapy with capsaicin or RTX, suggesting that plasticity in C-fiber afferents could form the neurogenic basis for DO (Geirsson, 1993; Fowler et al, 1994; Szallasi and Fowler, 2002). The emergence of a spinal reflex circuit activated by C-fiber bladder afferents represents a positive feedback mechanism (see Fig. 69-42) that may be unresponsive to voluntary control by higher brain centers and thereby be able to trigger involuntary voiding. The bladder ice-water urodynamic test has been suggested as a method to assess the C fiber-mediated micturition reflex. Although the ice-water test is consistent in a strictly controlled research environment, it has not been adequately sensitive or specific in routine clinical use (Chai et al, 1998; Chancellor et al, 1998).

Neurogenic DO has also been associated with decreased expression and decreased activity of BK channels in the bladder smooth

muscle (Hristov et al, 2013). BK channel activity (opening) underlies phase 2 and 3 hyperpolarization of the smooth muscle AP (see Fig. 69-16) and serves to quell detrusor myocyte excitability. Therefore, reduced expression and/or lessened function of the BK channels would necessarily lead to increased bladder contractions, hence DO. Although decreased BK expression and function in neurogenic DO help explain the mechanism behind neurogenic DO, the cause of decreased BK expression and function was not explored. This reference theorized that teleologically, decreased BK expression or function may be a consequence of a compensatory or adaptive mechanism in spinal cord injury patients that leads to increased detrusor smooth muscle contractility, allowing optimization of bladder emptying in the absence of normal innervation.

KEY POINTS: NEUROGENIC BLADDER

- Normal micturition is associated with a spinobulbospinal reflex mediated by lightly myelinated A δ afferents.
- Unmyelinated C fibers are normally relatively insensitive to gradual distention of the urinary bladder.
- After spinal cord injury, a capsaicin-sensitive C fiber-mediated spinal reflex develops and may play a role in the development of DO.
- Treatment of neurogenic DO patients with intravesical capsaicin or another C-fiber neurotoxin, RTX, produces symptomatic improvement in a subpopulation of these patients and reduces the density of TRPV1 immunoreactivity in nerve fibers and urothelium.
- The bladder ice-water urodynamic test has been suggested as a research method to assess the C fiber-mediated micturition reflex but is not practiced clinically.

Nocturia

It is becoming recognized that nocturia, especially when occurring in isolation from other LUTS, represents a symptom with its own unique set of possible physiologic causes (van Kerrebroeck and Andersson, 2014) including global polyuria, nocturnal polyuria, reduced bladder capacity, sleep disorders, heart failure, and circadian clock disorders. It has been recently shown that the mouse bladder itself exhibits circadian rhythms in expression of Cx43 (Negoro et al, 2012) and furthermore that Cx43 regulates bladder capacity in dark and light cycles of the mouse. During the light cycle, when the mouse is not active (equivalent to the human sleep cycle), Cx43 is downregulated, leading to increased bladder capacity (increased measure of volume voided per micturition). Conversely, during the dark cycle, when the mouse is awake and active, Cx43 is upregulated and bladder capacity is reduced (decreased volume voided per micturition). Transgenic animals with one of the circadian transcriptional regulators, *Cry*, knocked out developed loss of circadian oscillations of bladder capacity associated with loss of Cx43 expression oscillations. This study suggested that loss of the biologic clock mechanism in regulating Cx43 within the bladder may be a contributing mechanism to nocturia and nocturnal enuresis.

Bladder Outlet Obstruction

It is important to understand that the bothersome symptoms of patients with urethral obstruction are in most cases caused by the bladder. BOO, such as that in patients with BPH, often produces detrusor hypertrophy and DO (Gosling et al, 2000; Andersson and Wein, 2004). After chronic partial obstruction of the urethra in rats, the bladder enlarges and is about 15 times heavier, but it has the same shape as in control rats; the growth is mainly accounted for by muscle hypertrophy. The outer surface of the hypertrophic bladder is increased sixfold over that of the controls; the muscle is increased threefold in thickness and is more compact. Mitoses are not found, but there is a massive increase in muscle cell size

(Gabella and Uvelius, 1990). Obstruction-induced DO with irritative voiding symptoms has been attributed to denervation supersensitivity, because increased contractile responses of the bladder smooth muscle to cholinergic agonists have been observed (Speakman et al, 1987; Andersson and Wein, 2004). Alterations in detrusor contractility may also result from changes in contractile proteins (Uvelius et al, 1989; Cher et al, 1990; Chacko et al, 1999, 2004). Changes in the contractile proteins occur in developing bladders and also during bladder hypertrophy (Wang et al, 1995; Wu et al, 1995; Sjuve et al, 1996). Obstructed bladders induced expression of SM-A (DiSanto et al, 2003). The obstructed bladder developed higher levels of force, but with reduced cross-bridge cycling rates (Su et al, 2003). The ratio of SM1 to SM2 isoforms was also changed by BOO (Cher et al, 1996).

Brading and Turner (1994) proposed that all cases of DO have a common feature—detrusor smooth muscle change that predisposes it to unstable contraction. They have demonstrated that DO, as shown in a pig model of obstruction, may occur without participation of a micturition reflex. Mills and coworkers (2000) have also implicated abnormalities in the detrusor muscle and its pattern of innervation in IDO. Compared with the bladder wall in control subjects, there was evidence in the detrusor smooth muscle of altered spontaneous contractile activity consistent with increased electrical coupling of cells, patchy denervation of the detrusor, and potassium supersensitivity (Mills et al, 2000). One of the manifestations of this abnormality is a partial denervation of the detrusor smooth muscle. In rats with BOO induced by partial urethral ligation, acetylcholine release during electric stimulation of obstructed bladder muscle strips was significantly decreased 3 to 6 months after obstruction, along with a reduction in the number of nerve fibers in the obstructed bladder compared with control rats (Murakami et al, 2008). Partial denervation in obstructed bladder leads to various functional changes in smooth muscles including denervation supersensitivity of cholinergic (muscarinic) receptors (Speakman et al, 1987) and increases in purinergic receptor-mediated contractile responses as well as expression of purinergic receptors such as P2X₁ (Boselli et al, 2001; O'Reilly et al, 2001a). Changes in the cell-to-cell communication in detrusor muscles have also been indicated as a mechanism inducing DO, because there is an upregulation of Cx43, a gap-junction protein, in rats with DO induced by BOO (Christ et al, 2003; Mori et al, 2005; Li et al, 2007; Imamura et al, 2009; Miyazato et al, 2009). Increased expression of Cx43 is also identified in the bladders from patients with neurogenic DO (Haferkamp et al, 2004) or with urgency symptoms (Neuhaus et al, 2005). Thus increases in receptor-mediated muscle contractility and interaction among smooth muscle cells can result in coordinated myogenic contraction of the entire bladder and DO.

In addition, another population of cells in the bladder, known as *interstitial cells*, has been proposed to have a pacemaking role in spontaneous activity of the bladder (Andersson and Arner, 2004). Because it has been reported that the number of interstitial cells is increased in a guinea pig model of BOO (Kubota et al, 2008) and that c-KIT tyrosine kinase inhibitors, which inhibit interstitial cell activity, decreased the amplitude of spontaneous contractions in the guinea pig and human bladder (Biers et al, 2006; Kubota et al, 2006), interstitial cells may also be involved in the emergence of DO as a result of enhanced autonomous detrusor muscle activity.

Alterations also occur in neural networks in the CNS after obstruction of the LUT. BOO in rats causes enhancement of a spinal reflex (Steers and de Groat, 1988). Similarly, in humans with obstruction, a capsaicin-sensitive spinal reflex can be detected by the ice-water test (Chai et al, 1998; Hirayama et al, 2003, 2005). Within the spinal cord, obstruction stimulates an increased expression of GAP43 that has been associated with axonal sprouting after injury (Steers et al, 1996). These observations suggest an enhancement or de novo development of new spinal circuits after obstruction. Similar to spinal cord injury, obstruction causes hypertrophy of bladder afferent and efferent neurons (Steers et al, 1990, 1991). A hypothesis proposed is that these newly formed spinal circuits (neuroplasticity), once formed, do not reverse easily even if

obstruction is relieved because of persistent increased voiding frequency after relief of obstruction (Chai et al, 1999). An immunohistochemical analysis of the distribution and density of GAP43 showed that this protein was increased in the spinal cord in the region of the sacral parasympathetic nucleus in rats with BOO (Steers et al, 1996). Because this protein is a marker for axonal sprouting, its upregulation provides further indirect support for morphologic plasticity in afferent pathways after BOO. Nevertheless, these findings are not mutually exclusive of changes in the bladder smooth muscle, which are also likely to participate in the development of DO (Turner and Brading, 1997).

BOO appears to initiate the morphologic and electrophysiologic afferent plasticity through a mechanism involving NGF (see Fig. 69-42). NGF is responsible for the growth and maintenance of sympathetic and sensory neurons and has been shown to be responsible for neuronal regrowth after injury. NGF content is increased in obstructed bladders in animals and in humans (Steers et al, 1991). This increase in NGF content precedes the enlargement of bladder neurons and the development of urinary frequency (Steers et al, 1990, 1991). Moreover, blockade of NGF action with autoantibodies prevents the neural plasticity and urinary frequency after obstruction (Steers et al, 1996). In animals with persistent urinary frequency after relief of obstruction, NGF remains elevated in the bladder. These findings suggest a cause-and-effect relationship between NGF-mediated changes in bladder afferents and an enhanced spinal micturition reflex and urinary frequency associated with obstruction. Increased levels of urinary NGF have also been detected in BOO patients exhibiting OAB symptoms. Total urinary NGF levels were low in controls (0.5 pg/mL) and in patients with BOO without OAB symptoms (1 pg/mL), but considerably higher in patients with BOO and OAB symptoms (41 pg/mL) or BOO and DO (50 pg/mL). Investigators have examined urinary NGF before and after mid-urethral slings in females and found significantly increased NGF, corrected for creatinine, after mid-urethral slings (Chai et al, 2014), consistent with the finding that mid-urethral slings have a urodynamic cause of increased PdetQ-max (Kraus et al, 2011).

KEY POINTS: BLADDER OUTLET OBSTRUCTION

- Obstruction-induced DO with irritative voiding symptoms has been attributed to denervation supersensitivity, because increased contractile responses of the bladder smooth muscle to cholinergic agonists have been observed. Alterations in detrusor contractility may also result from changes in contractile proteins.
- Increases in receptor-mediated muscle contractility and interaction among smooth muscle cells have been observed with BOO.
- BOO in rats causes enhancement of a spinal reflex.
- Bladder tissue and urine NGF content is increased in obstructed bladders in animals.

Bladder Pain Syndrome and Interstitial Cystitis

BPS/IC is a syndrome characterized primarily by pain attributable to the bladder associated with urinary frequency and urgency. This condition has no defined cause, although this section will present data from animal studies that offer some theoretical origins. In Europe, the diagnosis of BPS/IC typically requires a bladder biopsy showing overt inflammation, so it is no surprise that histologic analysis of bladders from European patients with BPS/IC revealed marked edema, vasodilation, proliferation of nerve fibers, and infiltration of mast cells (Johansson and Fall, 1997). However, the diagnosis of BPS/IC in the United States is driven primarily by symptoms of chronic bladder pain and urinary frequency and urgency in the absence of urinary tract infection (UTI). In the United States, the diagnostic test, if performed, usually is hydrodistention of the bladder; and if a biopsy is performed,

rarely is it a deep biopsy of the bladder stroma. The appearance of glomerulations (petechiae) after hydrodistention of the bladder as a diagnostic criterion for BPS/IC was first described by Messing and Stamey (1978), although the diagnostic specificity of glomerulations was questioned (Waxman et al, 1998). It appears that the diagnostic approach to BPS/IC varies between the United States and Europe.

Traditionally, BPS/IC is categorized as an inflammatory bladder disease, although the cause of the inflammation remains elusive (and some question whether BPS/IC is even an inflammatory disease). Cyclophosphamide-induced hemorrhagic cystitis has been used to model for BPS/IC, although there is no relationship between these two entities. Although the chemical cystitis model is important in understanding the neurobiologic response to inflammation, the relevance to BPS/IC remains to be validated in translational clinical trials.

Chemical cystitis resulted in sensitizing mechanosensitive afferents and/or recruitment of afferents normally unresponsive to mechanical stimulation (i.e., silent C fibers) (Häbler et al, 1990; Sengupta and Gebhart, 1994; Dmitrieva and McMahon, 1996; Dmitrieva et al, 1997) and results in bladder inflammation. Proinflammatory agents, such as PGE₂, serotonin (5-HT), histamine, bradykinin, and adenosine, as well as neurotrophic factors such as NGF, which are released during chemical irritation, can induce bladder hyperactivity, as well as functional and chemical changes in C-fiber afferents that can lead to hyperexcitability (Dmitrieva and McMahon, 1996; Gold et al, 1996). For example, chronic chemical irritation of the bladder changes ion channel function in bladder afferent neurons and also increases the expression of various markers, including NOS (Vizzard et al, 1996), GAP43 (Vizzard and Boyle, 1999), PACAP, SP (Vizzard, 2001), and protease-activated receptors (Dattilio and Vizzard, 2005). The density of peptidergic afferent nerves also increases in the bladder mucosa and detrusor muscle (Dickson et al, 2006), and afferent peptidergic axons and parasympathetic efferent axons and varicosities are commonly observed in close contact, suggesting that sprouting of peripheral nerves occurs during chronic cystitis.

Cystitis also induces chemical changes in the spinal cord. Acute or chronic bladder irritation increases immediate early gene expression (*c-FOS*) in spinal neurons (Birder and de Groat, 1993), as well as increasing in GFR α 1-IR in the spinal dorsal horn and in areas associated with autonomic neurons (Forrest and Keast, 2008). There was a much smaller increase in GFR α 3-IR and no change in GFR α 2-IR. Changes in spinal cord mitogen-activated protein (MAP) kinases (extracellular signal-related kinases 1 and 2 [ERK1 and ERK2]) may also play a role in the facilitation of reflex voiding after bladder inflammation. Immunohistochemical studies revealed that, in noninflamed rat bladders, noxious but not non-noxious stimulation significantly increased phospho-ERK immunoreactivity (Cruz et al, 2007). After bladder inflammation, innocuous and noxious bladder distention increased the number of spinal neurons exhibiting phospho-ERK-immunoreactivity. ERK inhibition with intrathecal injection of PD98059 decreases reflex bladder activity and spinal *c-FOS* expression in animals with inflamed bladders but not in normal animals (Cruz et al, 2007). The results suggest that activation of spinal cord ERK contributes to acute and chronic inflammatory pain perception and mediates reflex bladder overactivity accompanying chronic bladder inflammation.

Direct evidence linking chronic bladder inflammation with functional changes in C-fiber afferents has been obtained in rat chronic cystitis models induced by cyclophosphamide or hydrochloric acid. In these models, the electrical properties of bladder afferent neurons (dissociated from L6 and S1 DRG), as well as the activity of the inflamed bladder, were measured. The majority of bladder afferent neurons from both control and cyclophosphamide-treated rats are capsaicin sensitive and exhibit high-threshold TTX-resistant APs and Na⁺ currents. However, neurons from rats with cystitis exhibit significantly lower thresholds for spike activation and show tonic rather than phasic firing characteristics (Hayashi et al, 2009b). Other significant changes in bladder afferent neurons from cystitis rats include increased somal diameter, increased input capacitance,

and decreased density of slowly inactivating A-type K^+ (K_A) currents (Yoshimura and de Groat, 1999; Hayashi et al, 2009b). In addition, the reduction in K_A currents in the hydrochloric acid-induced cystitis model was associated with reduced expression of the Kv1.4 α -subunit protein (which can form K_A channels) in bladder afferent neurons (Hayashi et al, 2009b), suggesting that the Kv1.4 subunit may be a molecule responsible for reduced K_A currents and increased excitability of bladder afferent neurons after cystitis. Previous experiments using cats with naturally occurring feline-type IC have also demonstrated that capsaicin-sensitive dorsal root ganglion neurons exhibit an increase in cell size and increase in firing rates of depolarizing current pulses because of a reduction in low-threshold K^+ currents (Sculptoreanu et al, 2005). Accordingly, chronic inflammation in BPS/IC could induce both cell hypertrophy and hyperexcitability of C-fiber bladder afferent neurons. If these changes in neuronal cell bodies also occur at C-fiber afferent terminals in the bladder wall, such hyperexcitability may represent an important mechanism for inducing pain in the inflamed bladder. This is supported by some clinical studies showing that C-fiber desensitization induced by intravesical application of capsaicin or RTX is effective for treating painful symptoms in patients with BPS/IC (Lazzeri et al, 1996, 2000), although a previous prospective, randomized clinical trial using intravesical RTX application was not effective in patients with BPS/IC (Payne et al, 2005).

There is little information available about the neuroplasticity of A δ -fiber bladder afferents in BPS/IC. However, a previous study (Roppolo et al, 2005) using single nerve fiber recordings has documented that A δ -fiber bladder afferents in cats with feline-type IC are more sensitive to bladder pressure changes than afferents in normal cats, suggesting that, in addition to neuroplasticity of C-fiber afferents, A δ -fiber bladder afferents might also undergo functional changes in BPS/IC.

Chronic bladder inflammation can also induce changes in functional properties of chemosensitive receptors such as TRPV1 in sensory neurons. Sculptoreanu and colleagues (2005) reported that DRG neurons obtained from cats with feline IC exhibit capsaicin-induced responses that are larger in amplitude and desensitize more slowly compared with those obtained from normal cats, and that altered TRPV1 receptor activity in cats with feline IC is reversed by an application of an inhibitor of PKC, suggesting that BPS/IC can alter TRPV1 activity owing to enhanced endogenous PKC activity. Because TRPV1 receptors are reportedly responsible, at least in part, for bladder overactivity elicited by cyclophosphamide-induced cystitis (Dinis et al, 2004), enhanced activity of TRPV1 receptors could contribute to bladder pain in BPS/IC. Studies in mice have also demonstrated a role of TRPV1 in cystitis. Systemic treatment with cyclophosphamide or intravesical administration of acrolein (the irritant metabolite of cyclophosphamide) produces not only bladder hyperactivity but also a sensitization of the paw withdrawal responses to mechanical stimulation of the paw (mechanical hyperalgesia). These responses do not occur in TRPV1 knockout mice (Charrua et al, 2007; Wang et al, 2008). In addition, GRC-6211, a new oral-specific TRPV1 antagonist, has been shown to decrease bladder overactivity and noxious bladder input in cystitis animal models (Charrua et al, 2009).

Afferent mechanisms can also explain coexistence of pelvic organ hyperalgesia, such as BPS/IC and IBS. The animal model for this phenomenon is pelvic organ cross-sensitization. In this model, the rectum is exposed to a chemical irritant, with the resultant development of bladder afferent sensitivity, involvement of the C-fiber afferents, and bladder mast cell activation (Ustinova et al, 2006; Pan et al, 2010; Ustinova et al, 2010; Asfaw et al, 2011; Malykhina et al, 2013).

NGF has also attracted attention as a mediator in the link between experimentally induced inflammation and pain signaling in BPS/IC. NGF is expressed widely in various cells, including urothelial cells, smooth muscle cells, and mast cells, and can activate mast cells to degranulate and proliferate. In the cyclophosphamide-induced chronic cystitis model in rats, increased expression of neurotrophic growth factors, such as NGF, brain-derived neurotrophic factor (BDNF), and CNTF in the bladder, as

well as phosphorylation of tyrosine kinase receptors (TrkA, TrkB) in bladder afferent neurons, has also been presented as direct evidence for increased neurotrophin-mediated signaling in chronic bladder inflammation (Vizzard, 2000; Qiao and Vizzard, 2002). The enhanced neurotrophic factor mechanisms are also associated with increased phosphorylated cAMP response-element binding protein (CREB) in bladder afferent neurons. Phosphorylated CREB, which is a transcription factor in the neurotrophin intracellular signaling pathway, is coexpressed with phosphorylated TrkA in a subpopulation of bladder afferent neurons (Qiao and Vizzard, 2004). RTX, a C-fiber neurotoxin, reduced cyclophosphamide-induced upregulation of phosphorylated CREB in DRG cells, suggesting that cystitis is linked with altered CREB phosphorylation in capsaicin-sensitive C-fiber bladder afferents (Qiao and Vizzard, 2004). These results suggest that upregulation of phosphorylated CREB may be mediated by a neurotrophin/TrkA signaling pathway, and that CREB phosphorylation may play a role as a transcription factor in LUT plasticity induced by chemical cystitis. In patients with BPS/IC, neurotrophins, including nerve growth factor, neurotrophin-3 (NT-3), and glial cell-derived neurotrophic factor (GDNF), have been detected in the urine (Okragly et al, 1999). Increased expression of NGF is also present in bladder biopsy specimens from women with IC (Lowe et al, 1997; Liu et al, 2014).

Exogenous NGF can induce bladder nociceptive responses and bladder overactivity in rats when applied acutely into the bladder lumen (Dmitrieva et al, 1997; Chuang et al, 2001) or chronically to the bladder wall or intrathecal space (Lamb et al, 2004; Yoshimura et al, 2006; Zvara and Vizzard, 2007). Conversely, application of NGF-sequestering molecules (TrkA-IgG or REN1820) can reduce referred thermal hyperalgesia elicited by bladder inflammation induced by intravesically applied turpentine oil (Jaggar et al, 1999) or bladder overactivity elicited by cyclophosphamide-induced cystitis (Hu et al, 2005), suggesting that increased NGF expression is directly involved in the emergence of bladder-related nociceptive responses in cystitis. A urothelially restricted NGF expression transgenic animal has also been created (Schneegelsberg et al, 2010). This animal has increased voiding frequency and evidence of increased pelvic pain. The suburothelial nerve fibers also vastly expanded with hyperinnervation of the bladder with significantly increased mast cells in the bladder stroma, consistent with the trophic effects of NGF on this cell type. However despite these data, targeted treatment with monoclonal anti-NGF antibody, tanezumab, did not prove efficacious in BPS/IC patients (Evans et al, 2011). This may be a result of phenotyping issues in enrollment, and perhaps an entry criterion of threshold level of increased NGF would be required to show an effect. As discussed in a prior section, the use of NGF as a biomarker in evaluation and management of LUTD is still unresolved (Ochodnick et al, 2011).

Purinergic mechanisms may also contribute to the bladder dysfunction in BPS/IC. ATP release from the urothelium is enhanced in patients and cats with BPS/IC (Sun et al, 2001; Birder et al, 2003). In conscious rats with cyclophosphamide-induced cystitis, purinergic receptor antagonists (pyridoxal-phosphate-6-azophenyl-2',4'-disulfonic acid [PPADS] and A-317491) reduced nonvoiding contractions and decreased voiding frequency (Ito et al, 2008). In in vitro whole-bladder pelvic afferent nerve preparations from rats with cyclophosphamide-induced cystitis, afferent nerve firing induced by bladder distention or by direct electric stimulation was markedly increased compared with firing in normal rats (Yu and de Groat, 2008). Exogenous purinergic agonists mimic the facilitatory effects of cyclophosphamide treatment, and P2X purinergic receptor antagonists suppress the effects of purinergic agonists and cystitis. These results suggest that endogenous purinergic agonists released in the inflamed bladder can enhance the excitability of bladder afferent nerves by activating P2X receptors. Patch clamp studies on bladder afferent neurons from rats revealed that chronic cyclophosphamide treatment increases the currents induced by purinergic agonists in both thoracolumbar and lumbosacral neurons (Dang et al, 2008). Analysis of the kinetics of the currents indicated that increased receptor expression and/or properties of homomeric P2X₃ in thoracolumbar neurons and P2X_{2/3} in

lumbosacral neurons contributes to the enhanced responses during cystitis. Investigations with human BPS/IC bladder urothelial specimens found that stretch of cultured bladder urothelial cells resulted in significantly increased ATP release (Sun et al, 2001) and increased P2X₃ expression on the cells (Sun and Chai 2004; Tempest et al, 2004).

Another animal model for BPS/IC is chronic psychological stress inflicted by water avoidance stress (WAS) testing. In this model, a rat is placed on a narrow surface suspended over water. The rat becomes stressed because it must maintain balance to avoid getting wet. Changes in bladder neurophysiology then can be studied after chronic WAS. It was found that chronic WAS significantly enhanced visceral organ, including bladder, nociceptive responses (Bradesi et al, 2005; Robbins et al, 2007; Smith et al, 2011). Chronic WAS was noted to cause increased mast cell activity in the bladder, which was blocked with treatment with melatonin and montelukast (Cikler et al, 2005). Because stress mechanisms involve the brain, it could be theorized that the development of visceral hyperalgesia with chronic WAS involves brain mechanisms, which now can be imaged with fMRI, in maintenance of the chronic pain state (Phillips and Clauw, 2011).

A search for urinary factors that might be a cause of BPS/IC resulted in discovery of antiproliferative factor (APF) by Keay and colleagues (1996, 1998). APF's structure was found to be a sialated glyconapeptide with sequence homology to a portion of the frizzled 8 protein of the Wnt signaling pathway (Keay et al, 2004). APF's receptor in the urothelial cell was found to be cytoskeletal-associated protein, CKAP4/p63 (Conrads et al, 2006). CKAP4/p63 is a palmitoylated protein that physically links the endoplasmic reticulum to the microtubules (Vedrenne et al, 2005). It is also a cell surface receptor for tissue plasminogen activator (Razzaq et al, 2003) and surfactant protein A (Gupta et al, 2006). CKAP4/p63 is a major substrate for a putative tumor suppressor enzyme, palmitoyl acyltransferase DHHC2 (Zhang et al, 2008), which may help explain APF's antiproliferative activity against urothelial cells. A mouse model in which intravesical application of APF resulted in similar bladder urothelial changes detected in human urothelium was published (Keay et al, 2012). Whether the understanding of APF biology can be integrated into care of BPS/IC patients remains to be seen.

KEY POINTS: BLADDER PAIN SYNDROME AND INTERSTITIAL CYSTITIS

- Histologic analysis of bladders from patients with BPS/IC often revealed marked edema, vasodilation, proliferation of nerve fibers, and infiltration of mast cells.
- NGF appears to be a key player in the link between inflammation and altered pain signaling. NGF is expressed widely in various cells, including urothelial cells, smooth muscle cells, and mast cells, and can activate mast cells to degranulate and proliferate.
- Application of NGF-sequestering molecules can reduce bladder overactivity elicited by cyclophosphamide-induced cystitis.
- Direct evidence linking chronic bladder inflammation with functional changes in C-fiber afferents has been obtained in rat chronic cystitis models. Chronic bladder inflammation can also induce changes in functional properties of chemosensitive receptors, such as TRPV1 in sensory neurons.

Aging

LUTS, such as increased voiding frequency, urgency, urgency incontinence, and poor bladder emptying, are common and troublesome problems in older men and women (Resnick, 1995; Naughton and Wyman, 1997; Nuotio et al, 2002). Previous studies have reported various changes in LUT function, including a reduction in bladder capacity, increased bladder sensation, and DO (Diokno et al, 1986;

Homma et al, 1994; Hald and Horn, 1998; Madersbacher et al, 1998, 1999; Nuotio et al, 2002). However, few studies have addressed the normal changes in the LUT that occur with aging. Studies by Pfisterer and colleagues (2006) have examined age-related changes in bladder function among 85 community-dwelling female volunteers and demonstrated that detrusor contractility, bladder sensation, and urethral pressure decline with age and that a reduction in bladder capacity associated with age may be related to DO rather than to aging itself, because bladder capacity did not decrease with age, but was smaller in subjects with DO (Pfisterer et al, 2006). Thus aging appears to induce hypofunction of the bladder and urethra in humans.

In animal studies, impaired bladder function, as evidenced by increased voided volume per micturition associated with a high micturition-pressure threshold, has also been demonstrated in aged rats compared with the young counterpart (Chun et al, 1988; Chai et al, 2000). In addition, aged rats exhibit reduced sensitivity of pelvic nerve afferents in response to increased bladder volume, but not pressure, and a reduction in the maximal bladder pressure generated during pelvic nerve stimulation (Hotta et al, 1995). In aging mice, bladder contractility was normal, but bladder afferent signaling was diminished (Smith et al, 2012a).

A significant linear reduction in the amount of acetylcholinesterase-positive nerve was observed with increasing age in the human bladder (Gilpin et al, 1986), suggesting reduced parasympathetic innervation of the aged bladder. It was also shown that expression of neuropeptides, such as CGRP and SP in lumbosacral DRG neurons, decreases with age (Mohammed and Santer, 2002) and that there is a marked reduction in the density of PACAP innervation of the subepithelial plexus and of the muscle layer of the bladder base, as well as slight reductions in CGRP and SP innervation of the muscle layer in old rats (Mohammed et al, 2002). Taken together, these results suggest that impaired activity of the aged bladder is likely, at least in part, a result of reduced activity of efferent and afferent nerves innervating the bladder.

Changes in the CNS in relation to LUT function have also been demonstrated in aged animals. Immunohistochemical analyses in aged rats revealed significant age-associated declines in the serotonergic (5-HT) and adrenergic innervation of various spinal cord regions, including the intermediolateral cell nucleus, sacral parasympathetic nucleus, dorsal gray commissure, and the ventral horn nucleus that contains the Onuf nucleus. However, 5-HT innervation of the sacral parasympathetic nucleus and tyrosine hydroxylase-like immunoreactivity in the ventral horn nucleus were maintained (Ranson et al, 2003). It was also shown that sympathetic preganglionic neurons in the L1-L2 spinal cord that project to the major pelvic ganglion exhibit a number of degenerative changes, such as reductions in the cell number, the length of their dendrites, and the synaptic contact made by glutamate-immunoreactive boutons onto the dendrites in aged rats, although these changes are not seen in parasympathetic preganglionic neurons in the L6-S1 spinal cord (Santer et al, 2002). Chai and colleagues also reported that frequent voiding produced by apomorphine-induced dopamine receptor activation is more pronounced in aged rats compared with young rats, suggesting that aged rats are more susceptible to altered central processing to induce bladder overactivity despite decline of baseline bladder function with aging (Chai et al, 2000). Hypoactivity of the bladder or the underactive bladder represents an unmet medical need moving forward in light of the aging populations in developed countries (Chancellor and Kaufman, 2008).

In contrast to altered nerve activity, there appears to be no significant change in detrusor contractile responses to cholinergic or electric stimulation between young and old animals (Chun et al, 1989; Longhurst et al, 1992; Yu et al, 1996; Lieu et al, 1997; Lin et al, 1997; Schneider et al, 2004b), although old rats have a reduced density of muscarinic receptors in the bladder (Schneider et al, 2004b). In contrast, there are some reports of age-related changes of the detrusor response to adrenergic stimulation (Latifpour et al, 1990). Most studies showed that detrusor contractile responses to α -adrenergic stimulation increased in old male and female rats (Saito et al, 1991, 1993; Nishimoto et al, 1995; Lin et al,

1997) in association with upregulation of α_{1D} -receptor expression in the bladder (Dmitrieva et al, 2008). However, another study showed no age-dependent changes in α_1 -adrenoceptor properties, such as phenylephrine-induced contractile responses, total receptor density, and mRNA expression of α_1 -adrenoceptor subtypes (α_{1A} , α_{1B} , and α_{1D}) in the rat bladder base and dome (Yono et al, 2006). The detrusor response to β -adrenergic stimulation is reduced in old male rats (Nishimoto et al, 1995; Lin et al, 1997), along with a reduction in the density of β -adrenergic receptors and decreased cAMP production (Nishimoto et al, 1995) in response to β -adrenergic stimulation. The combination of increased α -adrenergic excitatory response and decreased β -adrenergic inhibitory response results in a net contracting effect of norepinephrine on the aged bladder, in contrast to the relaxing effect of norepinephrine in the young bladder (Lin et al, 1997). However, the contribution of these changes in adrenoceptor properties to age-related alterations in LUT function is still to be determined.

KEY POINTS: AGING

- Bladder sensation and urethral pressure decline with age, and a reduction in bladder capacity associated with age may be related to DO rather than to aging itself, because bladder capacity was not seen to decrease with age but was smaller in subjects with DO. Thus aging appears to induce hypofunction of the bladder and urethra in humans.
- In contrast to altered nerve activity, there appears to be no significant change in detrusor contractile responses to cholinergic or electric stimulation between young and old animals.
- Most studies have shown that detrusor contractile responses to α -adrenergic stimulation increase and that detrusor-relaxing responses to β -adrenergic stimulation decrease in old rats.

Neuromodulation

Hypothesis of Mechanism of Action of Sacral Neuromodulation

Neuromodulation of the sacral nerves and, more recently, pudendal and posterior tibial nerves is now used for the treatment of

refractory OAB and urinary retention relating to pelvic floor dysfunction (Das et al, 2004; Leng and Chancellor, 2005; Herbison and Arnold, 2009). Some have criticized the inconsistency that electric stimulation of the sacral nerve can paradoxically inhibit the OAB and conversely promote bladder emptying in patients with idiopathic nonobstructive urinary retention. The effects of sacral neuromodulation may depend on electric stimulation of afferent axons in the spinal roots, which in turn modulate voiding and continence reflex pathways in the CNS. The afferent system is the most likely target, because beneficial effects can be elicited at intensities of stimulation that do not activate movements of striated muscles (Vadusek et al, 1986; Thon et al, 1991; de Groat et al, 1997). Sacral neuromodulation activates somatic afferent axons that modulate sensory processing and micturition reflex pathways in the spinal cord. Urinary retention and dysfunctional voiding can be resolved by inhibition of the guarding reflexes. DO can be suppressed by direct inhibition of bladder preganglionic neurons. Inhibition of interneuronal transmission in the afferent limb of the micturition reflex can also block DO. Thus the principle behind sacral neuromodulation can be summarized as somatic afferent inhibition of sensory processing in the spinal cord.

Rationale for Neuromodulation to Facilitate Voiding

In adults, brain pathways are necessary to turn off sphincter and urethral guarding reflexes to allow efficient bladder emptying. Thus spinal cord injury produces bladder-sphincter dyssynergia and inefficient bladder emptying by eliminating the brain mechanisms involved (Fig. 69-43). This may also occur after more subtle neurologic lesions in patients with idiopathic urinary retention, such as after a bout of prostatitis or UTI. Before the development of brain control of micturition, at least in animals, the stimulation of somatic afferent pathways passing through the pudendal nerve from the perineum can initiate efficient voiding by activating bladder efferent pathways and turning off the excitatory pathways to the urethral outlet (de Groat et al, 1993; Kruse and de Groat, 1993). Tactile stimulation of the perineum in the cat also inhibits the bladder-sympathetic reflex component of the guarding reflex mechanism. The sacral nerve stimulation may elicit similar responses in patients with urinary retention, and it may turn off excitatory outflow to the urethral outlet and promote bladder emptying. Because sphincter activity can generate afferent input to the spinal cord that can, in turn, inhibit reflex bladder activity, an indirect

Figure 69-43. When there is a sudden increase in intravesical pressure, such as during a cough, the urinary sphincter contracts by means of the spinal guarding reflex to prevent urinary incontinence (guarding reflex). The spinal guarding reflexes can be turned off by the brain for urination. In cases of neurologic diseases, the brain cannot turn off the guarding reflex, and retention can occur. Sacral nerve stimulation (SNS) restores voluntary micturition in cases of voiding dysfunction and urinary retention but inhibits the guarding reflex.

Figure 69-44. The voiding reflex involves afferent neurons from the bladder that project on spinal tract neurons that ascend to the brain. Descending pathways connect to parasympathetic efferent nerves to contract the bladder (bladder-bladder reflex). A spinal bladder-urethra reflex is activated by a similar bladder afferent innervation. In cases of supraspinal dysfunction, overactive micturition reflexes occur. Sacral nerve stimulation (SNS) inhibits urinary urgency, frequency, and urge incontinence by inhibiting the bladder-bladder and bladder-urethra reflexes.

benefit of suppressing sphincter reflexes would be a facilitation of bladder activity.

Rationale for Neuromodulation to Inhibit the Overactive Bladder

Several reflex mechanisms may be involved in the sacral neuromodulation suppression of DO. Afferent pathways projecting to the sacral cord can inhibit bladder reflexes in animals and humans. The source of afferent input may be from sphincter muscles, distal colon, rectum, anal canal, vagina, uterine cervix, and cutaneous afferents from the perineum (Fig. 69-44). As mentioned previously, two mechanisms have been identified in animals for somatic and visceral afferent inhibition of bladder reflexes. The most common mechanism is suppression of interneuronal transmission in the bladder reflex pathway (de Groat and Theobald, 1976; Kruse et al, 1990; Kruse and de Groat, 1993). It is assumed that this inhibition occurs, in part, on the ascending limb of the micturition reflex and therefore blocks the transfer of information from the bladder to the PMC. This action would prevent involuntary (reflex) micturition but not necessarily suppress voluntary voiding that would be mediated by descending excitatory efferent pathways from the brain to the sacral parasympathetic preganglionic neurons. A second inhibitory mechanism is mediated by a direct inhibitory input to the bladder preganglionic neurons. This can be induced by electric stimulation of the pudendal nerve or by mechanical stimulation of the anal canal and distal bowel. It is not elicited by tactile stimulation of penile or perineal afferents; this mechanism would be much more effective in turning off bladder reflexes, because it would directly suppress firing in the motor outflow from the spinal cord.

Pudendal Nerve Stimulation

The pudendal nerve is a peripheral branch of the sacral nerve roots, and stimulating the pudendal allows afferent stimulation to all three of the sacral nerve roots (S2, S3, S4), and that may raise the stimulation threshold needed for micturition and inhibit detrusor activity. Because this is a more peripheral nerve, it is less likely that stimulation of the sciatic and sural nerves will occur, thus decreasing the potential risk for discomfort in the thighs, calves, and feet as seen on occasion with sacral stimulation at the S3 nerve root. The pudendal nerve arises from the sacral plexus within the pelvis; it must go around the pelvic floor to reach the ischioanal fossa. In the pelvis, it runs on the piriformis and then passes laterally through

the greater sciatic foramen to enter the gluteal region. Here it lies inferior to the piriformis as does the sciatic nerve, the inferior gluteal neurovascular bundle, and the nerve to the quadratus femoris. The pudendal nerve curls around the spine of the ischium, lying superficial to the sacrospinous ligament, and then passes into the lesser sciatic notch to enter the ischioanal fossa. The nerve then divides into the inferior rectal, the perineal, and the dorsal nerve of the penis or clitoris.

Afferent pudendal nerve stimulation has been demonstrated to inhibit the micturition reflex, abolish uninhibited detrusor contractions, and increase bladder capacity in animals and humans (Fall and Lindstrom, 1991). Peters and colleagues (2005) compared the effectiveness of sacral and pudendal nerve stimulation for voiding dysfunction in a prospective, single-blind, randomized crossover trial including 30 patients (22 with urgency or frequency, 5 with urgency incontinence, and 3 with urinary retention) scheduled for sacral implantation of a tined quadripolar lead who consented to the placement of a second pudendal lead. Twenty-four of the 30 patients demonstrated a significant clinical response and had an implantable pulse generator placed. Sacral nerve stimulation resulted in 46% improvement in symptoms, whereas pudendal nerve stimulation demonstrated 63% improvement in symptoms. Urgency-incontinence episodes were reduced by approximately 47%; however, this did not reach statistical significance because of small sample size ($n = 5$).

Inhibitory and Excitatory Stimulation Frequencies of the Pudendal-Bladder Reflexes

The exact mechanism of action of neuromodulation is unknown. In addition, there are no studies involving neuromodulation that look at programming parameters (pulse width, intensity, or frequency) and their impact on voiding function. The pudendal nerve may have a dual mechanism depending on the frequency and continuity of stimulation. A recent study by Tai and colleagues (2007) in anesthetized spinal cord-injured cats demonstrated that at 3 Hz, stimulation of the pudendal nerve inhibited bladder function and decreased bladder pressures, whereas intermittent stimulation at 20 Hz improved the efficiency of the bladder to empty (Tai et al, 2007). Furthermore, the clinical outcomes of continuous (which potentially can fatigue the urethral sphincter and accommodate the nerve) and intermittent stimulation have not been explored. It would directly suppress firing in the motor outflow from the spinal cord.

Figure 69-45. Schematic diagram demonstrating normal fusion and release of acetylcholine from nerve terminals through interaction of vesicle and membrane-bound (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor [SNARE]) proteins. Parasympathetic nerves innervate the urinary bladder (*inset*) with (A) nerve terminal in an unactivated state displaying numerous vesicles containing the neurotransmitter acetylcholine. B, After nerve activation, assembly of the SNARE protein complex (e.g., synaptobrevin, SNAP-25, and syntaxin) leads to (C) release of acetylcholine and activation of postjunctional muscarinic receptors, resulting in bladder contraction.

OnabotulinumtoxinA Neuromodulation

In recent years, there has been increasing evidence for the therapeutic efficacy of OBTX for the treatment of various urethral and bladder dysfunctions (Smith and Chancellor, 2004; Apostolidis and Fowler, 2008).

Botulinum toxins act by inhibiting ACh release at the presynaptic cholinergic nerve terminal, thereby inhibiting striated and smooth muscle contractions. The toxins are synthesized as single-chain polypeptides with a molecular weight of about 150 kD (Das-Gupta, 1994). Initially, the parent chain is cleaved into its active dichain polypeptide form, consisting of a heavy chain (approximately 100 kD) connected by a disulfide bond to a light chain (approximately 50 kD) with an associated zinc atom (Schiavo et al, 1992). Four steps are required for toxin-induced paralysis: binding of the toxin heavy chain to an as yet unidentified nerve terminal receptor, internalization of the toxin within the nerve terminal, translocation of the light chain into the cytosol, and inhibition of neurotransmitter release. Neurotransmitter release involves the ATP-dependent transport of the vesicle from the cytosol to the plasma membrane (Barinaga, 1993). Vesicle docking requires the interaction of various cytoplasm, vesicle, and target membrane proteins (i.e., soluble *N*-ethylmaleimide-sensitive factor attachment

protein receptor [SNARE] proteins), some of which are specifically targeted with clostridial neurotoxins (Fig. 69-45). For example, OBTX cleaves the cytosolic translocation protein SNAP-25, thus preventing vesicle fusion with the plasma membrane (Fig. 69-46) (Schiavo et al, 1993).

Seven immunologically distinct neurotoxins are designated types A, B, C, D, E, F, and G. Clinically, the urologic community has used commercial preparations of OBTX to treat patients with neurogenic and IDO (Dykstra et al, 1988; Dykstra and Sidi, 1990; Schurch et al, 1996; Petit et al, 1998; Schurch et al, 2000; Apostolidis et al, 2009). Although ACh release from bladder parasympathetic efferent terminals is a likely target of OBTX treatment, suppression of bladder afferent activity with OBTX treatment is also evident because the reduction of urgency symptom in patients with neurogenic detrusor overactivity and IDO is associated with reduced expression of the capsaicin receptor (TRPV1) and the ATP receptor (P2X₃) in C fibers (Apostolidis et al, 2005a). In addition, in basic research, botulinum toxins are shown to suppress not only efferent nerve activity by inhibition of the release of ACh but also afferent nerve activity by release of inhibition of neurotransmitters, such as SP and CGRP, from sensory terminals (Chuang et al, 2004; Dressler et al, 2005; Ikeda et al, 2012). There is also evidence that the toxin can reduce the release of ATP (and

Figure 69-46. Diagram of parasymphathetic nerve terminal demonstrating (A) binding of the toxin heavy chain to an as yet unidentified receptor and internalization of the toxin within the nerve terminal; (B) translocation of the light chain into the cytosol; and (C) inhibition of neurotransmitter release by cleavage of specific synaptosome-associated membrane receptor proteins. A to G represent different botulinum toxin serotypes.

possibly other mediators) from urothelial cells in control urothelial cells (Hanna-Mitchell et al, 2015) and in spinalized rats (Khera et al, 2004; Smith et al, 2005, 2008). A recent study using lipotoxin (liposomes as a carrier for OBTX) demonstrated that the urothelium is also a site of action for this treatment (Kuo et al, 2014). Thus the use of the toxins has been expanded to treat women with pelvic floor spasticity, as well as patients with non-neurogenic OAB and even BPS (Smith et al, 2003; Smith and Chancellor, 2004; Smith et al, 2005; Apostolidis and Fowler, 2008). The efficacy of botulinum toxins has also been identified in patients with BPH, in whom OBTX injection into the prostate induced an atrophy of the prostate by inducing apoptosis, inhibiting proliferation, and downregulating α_{1A} -adrenergic receptors (Chuang et al, 2006). However, in a large phase 2 randomized, placebo-controlled, dose-ranging OBTX (transperineal or transrectal intraprostatic injection of OBTX into transitional zone) trial for BPH symptoms, the findings were primarily negative (Marberger et al, 2013). There was no difference in the outcomes between placebo and any of the dose ranges of OBTX (100 U, 200 U, and 300 U) used. Only in a subanalysis of the 200-U OBTX dose, and only in subjects with prior α -blocker use, did the investigators find a significant difference between placebo and OBTX.

The use of intradetrusor OBTX injection versus oral antimuscarinics in idiopathic OAB with urgency incontinence was studied in a randomized comparative efficacy trial (Visco et al, 2012). Reduction in urgency incontinence episodes per day was not different

between OBTX and antimuscarinics, but the rate of complete resolution of urgency incontinence was significantly higher in the OBTX-treated subjects. The antimuscarinic-treated subjects had a higher rate of dry mouth, but lower rates of catheter use and UTI.

FUTURE RESEARCH

Research holds the key to advancing the evaluation, treatment, and prevention of LUTD. As research delves deeper into physiology and pharmacology of the LUT, it is vitally important to continually translate research findings into clinical advances. A continuing dialogue between the clinician and scientist must be maintained. Newer treatments such as OBTX, β_3 -agonists, sacral neuromodulation, and posterior tibial neurostimulation have been implemented into our armamentarium, but what is next on the horizon? Although traditional physiologic, pharmacologic, and neurobiologic approaches will continue to be important, this field will require innovations that have advanced other fields. These would include incorporation of "omics" techniques—genomics, proteomics, transcriptomics, and metabolomics. These techniques use the latest high-throughput technology to screen the entire genome or all of the proteins, mRNA, or metabolites within a biologic specimen in attempts to find signature abnormalities that could point to biologic causes for the condition being studied. Through use of this technology, coupled with "omics" techniques, we will have to

develop more accurate phenotyping of patients with LUTD. Currently, we are “stuck” on refining symptom phenotyping, when all other fields are moving to biologic phenotyping. Phenotyping based on biology might help prognosticate outcomes of LUTD treatment, determine history of LUTD conditions, and point to new biologic pathways involved in LUTD.

The questions for future research may include the following:

1. Can we prevent development of any form of LUTD based on our understanding of pathophysiologic mechanisms?
2. Can we develop biomarkers to better phenotype different forms of LUTD?
3. Can the biomarkers be used to prognosticate treatment outcomes?
4. Can the biomarker search result in novel targets for treatment?
5. Can genomics studies point to susceptibility genes for the development of LUTD?
6. Can the afferent signals from the LUT be modulated to treat afferent neurourology conditions?
7. Is the bladder urothelium targetable to treat different forms of LUTD?
8. Will a pharmacologic or physiologic intervention be developed that will successfully treat the underactive detrusor so self-catheterization is obsolete?

Normal Lower Urinary Tract Function: Overview

Mechanisms Underlying the Two Phases of Function: Overview

Micturition Cycle: Simplification and Overview

Abnormalities of Filling/Storage and Emptying/Voiding: Overview of Pathophysiology

Classification Systems

The lower urinary tract (LUT) functions as a group of inter-related structures whose joint function in an adult is to bring about efficient and low-pressure bladder filling, low-pressure urine storage with perfect continence, and periodic complete voluntary urine expulsion also at low pressure. Appropriate sensation should accompany the function of the LUT, meaning that a sense of deferrable bladder fullness should gradually occur between voluntary voids up to a volume that is sufficient to prevent urinary frequency and without any pain or sudden compelling desires to void that are difficult to defer (urgency). Because the LUT in adults is normally under voluntary neural control, it is clearly different from other visceral organs innervated by the autonomic nervous system, whose regulation is solely by involuntary mechanisms.

For the purposes of description and teaching, the micturition cycle is best divided into two relatively discrete phases: bladder filling/urine storage and bladder emptying/voiding. The micturition cycle normally displays these two modes of operation in a simple on-off fashion. The cycle involves switching from inhibition of the voiding reflex and activation of the storage reflexes to inhibition of the storage reflexes and activation of the voiding reflex and back again. This chapter begins with a functional, physiologic, and pharmacologic overview of normal and abnormal LUT function. A simple way of looking at the pathophysiology of all types of voiding dysfunction is then presented, followed by a discussion of various systems of classification and categorization. Consistent with my own philosophy and prior attempts to make the understanding, evaluation, and management of voiding dysfunction as logical and simple as possible (Wein, 1981; Wein and Barrett, 1988; Wein, 2002), a functional and practical approach is favored.

As an apology and explanation to significant contributors to the field whose works have not been specifically referenced by name as frequently as they could have been, citations have been chosen primarily because of their comprehensive review or informational content and not because of originality or initial publication on a particular subject except where noted.

NORMAL LOWER URINARY TRACT FUNCTION: OVERVIEW

Two-Phase Concept of Function: Filling/Storage and Emptying/Voiding

Whatever disagreements exist regarding the anatomic, morphologic, physiologic, pharmacologic, and mechanical details involved in the storage and the expulsion of urine by the LUT, I have always

taken the simple view that the “experts” would agree on certain general points (Wein, 1981; Wein and Barrett, 1988; Wein, 2007; Wein and Moy, 2007). The first is that the micturition cycle involves two relatively discrete processes: (1) bladder filling and urine storage and (2) bladder emptying or voiding. The second is that, whatever the details involved, one can succinctly summarize these processes from a conceptual point of view as follows:

Bladder filling and urine storage require:

- Accommodation of increasing volumes of urine at a low detrusor pressure (normal compliance) and with appropriate sensation.
- A bladder outlet that is closed at rest and remains so during increases in intra-abdominal pressure.
- Absence of involuntary bladder contractions (detrusor overactivity [DO]).

Bladder emptying/voiding requires:

- A coordinated contraction of the bladder smooth musculature of adequate magnitude and duration.
- A concomitant lowering of resistance at the level of the smooth and striated sphincter (no functional obstruction).
- Absence of anatomic (as opposed to functional) obstruction.

The **smooth sphincter** refers to the smooth musculature of the bladder neck and proximal urethra. This is a physiologic but not an anatomic sphincter and one that is not under voluntary control. The **striated sphincter** refers to the striated musculature that is a part of the outer wall of the proximal urethra in males and females (this portion is often referred to as the **intrinsic or intramural striated sphincter or rhabdosphincter**) and the bulky skeletal muscle group that closely surrounds the urethra at the level of the membranous portion in males and primarily the middle segment in females (often referred to as the **extrinsic or extramural striated sphincter**). The extramural portion is the classically described **external urethral sphincter** and is under voluntary control (for a detailed discussion see Chapter 69) (Brading et al, 2001; DeLancey et al, 2002; Zderic et al, 2002; Bircar et al, 2013).

MECHANISMS UNDERLYING THE TWO PHASES OF FUNCTION: OVERVIEW

This section briefly summarizes pertinent points regarding the physiology and pharmacology of the various mechanisms underlying normal bladder filling/storage and emptying/voiding that constitute

the pathophysiologic mechanisms seen in the various types of dysfunction of the LUT. The general information is consistent with that detailed in Chapter 69 and in previous source materials and their supporting references (Wein and Barrett, 1988; de Groat et al, 1993, 1999; de Groat and Yoshimura, 2001; Zderic et al, 2002; Andersson and Arner, 2004; Andersson and Wein, 2004; Morrison et al, 2005; Mostwin et al, 2005; de Groat, 2006; Yoshimura and Chancellor, 2007; Fowler et al, 2008; Michel and Barendrecht, 2008; Beckel and Holstege, 2011; Birder et al, 2013; Koelbl et al, 2013; Ochodnick et al, 2013; and Andersson, 2014). Other specific references are provided only when particularly unique or applicable.

Bladder Response during Filling

The normal adult bladder response to filling at a physiologic rate is an almost imperceptible change in intravesical and detrusor pressure. During at least the initial stages of bladder filling, after unfolding of the bladder wall from its collapsed state, this high compliance (Δ volume/ Δ pressure) of the bladder is due primarily to its elastic and viscoelastic properties. Elasticity allows the constituents of the bladder wall to stretch to a certain degree without any increase in tension. Viscoelasticity allows stretch to induce an increase in tension followed by a decay ("stress relaxation") when the filling (stretch stimulus) slows or stops. The viscoelastic properties are considered to be primarily due to the characteristics of the extracellular matrix in the bladder wall. Andersson and Arner (2004) cite references demonstrating that the main extracellular components are elastic fibers and collagen fibrils present in the serosa, between muscle bundles, and between the smooth muscle cells in the muscle bundles. Brading and colleagues (1999) state that they believe there is continuous contractile activity in the smooth muscle cells to adjust their length during filling but without the type of synchronous activity that would increase intravesical pressure, would impede filling, and could cause urinary leakage. Clinically and urodynamically, the bladder seems "relaxed." The urothelium also expands but must preserve its barrier function while doing so.

There may also be a non-neurogenic active component to the storage properties of the bladder. Hawthorn and colleagues (2000) have suggested that an as yet unidentifiable relaxing factor is released from the urothelium during filling and storage, and Andersson and Wein (2004) and Andersson (2014) have suggested that urothelium-released nitric oxide may have an inhibitory effect on afferent mechanisms as well.

The viscoelastic properties of the stroma (bladder wall less smooth muscle and epithelium) and the urodynamically non-contractile state of the detrusor muscle account for the passive mechanical properties and normal bladder compliance seen during filling. The main components of the stroma are collagen and elastin. In the usual clinical setting, filling cystometry seems to show a slight increase in intravesical pressure, but Klevmark (1974, 1999) elegantly showed that this pressure increase is a function of the fact that cystometric filling is carried out at a greater than physiologic rate and that, at physiologic filling rates, there is essentially no increase in bladder pressure until bladder capacity is reached.

When the collagen component of the bladder wall increases, compliance decreases. This can occur with chronic inflammation, bladder outlet obstruction, neurologic decentralization, and various other types of injury. Bladder muscle hypertrophy, which can result from outlet obstruction, can also result in decreased compliance because hypertrophic muscle is said to be less elastic than normal detrusor; it also can synthesize increased amounts of collagen (Mostwin, 2006). Once decreased compliance has occurred because of a replacement by collagen of other components of the stroma, it is generally unresponsive to pharmacologic manipulation, hydraulic distention, or nerve section. Most often, under those circumstances, augmentation cystoplasty is required to achieve satisfactory reservoir function.

Does the nervous system affect the normal bladder response to filling? At a certain level of bladder filling, spinal sympathetic reflexes facilitatory to bladder filling/storage are clearly evoked in

animals, a concept developed over the years by de Groat and others (see Chapter 69) (de Groat et al, 1993; de Groat and Yoshimura, 2001; Chancellor and Yoshimura, 2002; Zderic et al, 2002; Yoshimura and Chancellor, 2007), who have also cited indirect evidence to support such a role in humans. This inhibitory effect is thought to be mediated primarily by sympathetic modulation of cholinergic ganglionic transmission. Through this reflex mechanism, two other possibilities exist for promoting filling/storage. One is neurally mediated stimulation of the predominantly α -adrenergic receptors (α_1) in the area of the smooth sphincter, the net result of which would be to cause an increase in resistance in that area. The second is neurally mediated stimulation of the predominantly β -adrenergic receptors (β_3 inhibitory) in the bladder body smooth musculature, which would cause a decrease in bladder wall tension. McGuire and colleagues (1983) have also proposed a direct inhibition of detrusor motor neurons in the sacral spinal cord during bladder filling related to increased afferent pudendal nerve activity generated by receptors in the striated sphincter. Good evidence also seems to exist to support an inhibitory effect of other neurotransmitters (e.g., glycine, γ -aminobutyric acid, opioids, purines, the noradrenergic system) on the micturition reflex at various levels of the neural axis. Bladder filling and consequent wall distention may also result in the release of factors from the urothelium that may influence contractility (e.g., acetylcholine, adenosine triphosphate, nitric oxide, prostaglandins, other peptides, as yet unidentified inhibitory factors).

Outlet Response during Filling

There is a gradual increase in proximal urethral pressure during bladder filling, contributed to at least by the striated sphincteric element and perhaps by the smooth sphincteric element as well. The increase in urethral pressure seen during the filling/storage phase of micturition can be correlated with an increase in efferent pudendal nerve impulse frequency and in electromyographic activity of the striated sphincter. This constitutes the efferent limb of a spinal somatic reflex, the so-called **guarding reflex**, which results in a gradual increase in striated sphincter activity during normal bladder filling and storage. Although it seems logical and compatible with neuropharmacologic, neurophysiologic, and neuromorphologic data to assume that the muscular component of the smooth sphincter also contributes to the change in urethral response during bladder filling, probably through sympathetically induced contraction, it is extremely difficult to prove this experimentally or clinically. The direct and circumstantial evidence in favor of such a hypothesis has been summarized by Wein and Barrett (1988), Brading (1999), Andersson and Wein (2004), Birder and colleagues (2013), and Andersson (2014).

The passive properties of the urethral wall warrant mention because these undoubtedly play a role in the maintenance of continence (Zinner et al, 1983; Brading, 1999). Urethral wall tension develops within the outer layers of the urethra; however, urethral pressure is a product not only of the active characteristics of smooth and striated muscle but also of the passive characteristics of the elastic, collagenous, and vascular components of the urethral wall because this tension must be exerted on a soft or plastic inner layer capable of being compressed to a closed configuration—the **"filler material"** representing the submucosal portion of the urethra. The softer and more pliable this area is, the less pressure is required by the tension-producing area to produce continence. Finally, whatever the compressive forces, the lumen of the urethra must be capable of being obliterated by a watertight seal. This **"mucosal seal mechanism"** explains why a thin-walled rubber tube requires less pressure to close an open end when the inner layer is coated with a fine layer of grease than when it is not, the latter case being akin to scarred or atrophic urethral mucosa.

Voiding with a Normal Bladder Contraction

Although many factors are involved in the initiation of micturition, in adults, increased intravesical pressure producing the sensation

of distention is primarily responsible for the initiation of normal voluntarily induced emptying of the LUT. Although the origin of the parasympathetic neural outflow to the bladder, the pelvic nerve, is in the sacral spinal cord, the actual coordinating center for the micturition reflex in an intact neural axis is in the rostral brainstem. The complete neural circuit for normal micturition includes the ascending and descending spinal cord pathways to and from this area and the facilitatory and inhibitory influences from other parts of the brain, particularly the cerebral cortex. The final step in voluntarily induced micturition involves inhibition of the somatic neural efferent activity to the striated sphincter and an inhibition of all aspects of any spinal sympathetic reflexes evoked during filling. Efferent parasympathetic pelvic nerve activity is ultimately what is responsible for a highly coordinated contraction of the bulk of the bladder smooth musculature.

A decrease in outlet resistance occurs with adaptive shaping or funneling of the relaxed bladder outlet. Besides the inhibition of any continence-promoting reflexes that have occurred during bladder filling, the change in outlet resistance may also involve an active relaxation of the smooth sphincter area through a noradrenergic noncholinergic mechanism, proposed to be mediated by nitric oxide (Andersson and Arner, 2004; Andersson and Wein, 2004; Birder et al, 2013; Andersson, 2014). The adaptive changes that occur in the outlet are probably also due at least in part to the anatomic interrelationships of the smooth muscle of the bladder base and proximal urethra. Longitudinal smooth muscle continuity (see Chapter 69) (Mostwin, 2006) would promote shortening and widening of the proximal urethra during a coordinated emptying bladder contraction. Other reflexes that are elicited by bladder contraction and by the passage of urine through the urethra may reinforce and facilitate complete bladder emptying. Superimposed on these autonomic and somatic reflexes are complex, modifying supraspinal inputs from other central neuronal networks. These facilitatory and inhibitory impulses, which originate from several areas of the nervous system, allow the full conscious control of micturition in the adult.

Urinary Continence during Abdominal Pressure Increases

During voluntarily initiated micturition, the bladder pressure becomes higher than the outlet pressure, and certain adaptive changes occur in the shape of the bladder outlet with consequent passage of urine into and through the proximal urethra. One could reasonably ask: **Why do such changes not occur with increases in intravesical pressure that are similar in magnitude but that are produced only by changes in intra-abdominal pressure such as straining or coughing?** First, a coordinated bladder contraction does not occur in response to such stimuli, emphasizing the fact that increases in total intravesical pressure are by no means equivalent to emptying ability. Second, for urine to flow into and through the proximal urethra in an individual who does not have sphincteric incontinence, there must be (1) an increase in intravesical/detrusor pressure that is primarily a product of a coordinated, neurally mediated bladder contraction and that is (2) associated with characteristic tension and conformational changes in the bladder neck and proximal urethral areas.

Assuming that the bladder outlet is competent at rest, a major factor required for the prevention of urinary leakage during increases in intra-abdominal pressure is the presence of **at least equal pressure transmission to the proximal urethra (the mid-urethra as well in women) during such activity.** This phenomenon was first described by Enhorning (1961) and has been confirmed in virtually every urodynamic laboratory since that time. **Failure of this mechanism is an invariable correlate of effort-related urinary incontinence in women and men.** The urethral closure pressure increases with increments in intra-abdominal pressure, indicating that active muscular function related to a reflex increase in striated sphincter activity or other factors that increase urethral resistance is also involved in preventing such leakage. Tanagho (1978) was the first to provide direct evidence of this. A more complete

description of the factors involved in sphincteric incontinence can be found later in this chapter, in Chapters 69 and 74, and in the work of Koelbl and associates (2013).

Sensory Aspects

Most of the afferent input from the bladder and urethra reaches the spinal cord through the pelvic nerve and dorsal root ganglia, and some reaches the spinal cord through the hypogastric nerve. Afferent input from the striated muscle of the sphincter and pelvic floor travels in the pudendal nerve. The most important afferents for initiating and maintaining normal micturition are those in the pelvic nerve, relaying to the sacral spinal cord. These convey impulses from tension, volume, and nociceptive receptors located in the serosal, muscle, and urothelial and suburothelial layers of the bladder and urethra. In a neurologically normal adult, the sensation of filling and distention, but not urgency or pain, develops during normal filling/storage and initiates the reflexes responsible for emptying/voiding (see Chapter 69) (de Groat and Yoshimura, 2001; Chancellor and Yoshimura, 2002; Morrison et al, 2005; Birder et al, 2013). Alterations in this finely tuned pathway can be responsible for significant alterations in LUT function.

MICTURITION CYCLE: SIMPLIFICATION AND OVERVIEW

Filling/Storage

Bladder accommodation during filling is a primarily passive phenomenon dependent on the elastic and viscoelastic properties of the bladder wall and the lack of parasympathetic excitatory input. An increase in outlet resistance occurs by means of the striated sphincter somatic guarding reflex. In some species, a sympathetic reflex also contributes to storage by (1) increasing outlet resistance through increased tension in the smooth sphincter, (2) inhibiting bladder contractility through an inhibitory effect on parasympathetic ganglia, and (3) causing a decrease in tension of bladder body smooth muscle. Continence is maintained during increases in intra-abdominal pressure by the intrinsic competence of the bladder outlet (bladder neck and proximal urethra/mid-urethra) and the pressure transmission ratio to this area with respect to the intravesical contents. A further increase in striated sphincter activity, on a reflex basis, is also contributory.

Emptying/Voiding

Emptying (voiding) can be voluntary or involuntary and involves an inhibition of the spinal somatic and sympathetic reflexes and activation of the vesical parasympathetic pathways, the organizational center for which is in the rostral brainstem. Initially, there is a decrease in outlet resistance, mediated not only by the cessation of the somatic and sympathetic spinal reflexes but possibly also by a relaxing factor released by parasympathetic stimulation or by some effect of bladder smooth muscle contraction itself. A highly coordinated parasympathetically induced contraction of the bulk of the bladder smooth musculature occurs, with shaping or funneling of the relaxed outlet, owing at least in part to smooth muscle continuity between the bladder base and the proximal urethra. With amplification and facilitation of the bladder contraction from other peripheral reflexes and from spinal cord supraspinal sources, and in the absence of anatomic or functional obstruction between the bladder and urethral meatus, complete emptying occurs.

ABNORMALITIES OF FILLING/STORAGE AND EMPTYING/VOIDING: OVERVIEW OF PATHOPHYSIOLOGY

Excluding psychological reasons, the pathophysiology of failure of the LUT in an adult to fill with or store urine adequately or to empty adequately must logically be secondary to reasons related to the bladder, the outlet, or a combination (Wein, 1981; Wein and Barrett, 1988). This division provides a logical rationale for discussion and classification of all types of LUT dysfunction. (Box 70-1).

There are some types of dysfunction that represent combinations of filling/storage and emptying/voiding abnormalities (e.g., DO and sphincter dyssynergia in a patient with suprasacral spinal cord injury; DO during filling/storage, detrusor underactivity during emptying), but within this scheme these have become readily understandable and detectable, and the treatment dilemmas have been logically described. Failure in either category is not absolute but more often is relative. The system can be easily expanded and made more detailed to include etiologic or specific urodynamic connotations (Box 70-2). However, the simplified system is perfectly workable and avoids argument in complex situations in which the exact etiology or mechanism for a dysfunction cannot be agreed on.

Using this concept, all aspects of urodynamic and video-urodynamic evaluation can be conceptualized as to exactly what they evaluate in terms of either bladder or outlet activity during filling/storage or emptying/voiding (Table 70-1). Treatments can be classified under these broad categories as to whether they facilitate filling/storage or emptying/voiding and whether they do so by acting primarily on the bladder or on one or more components of the bladder outlet (Boxes 70-3 and 70-4).

Filling/Storage Failure

Absolute or relative failure of the bladder to fill with and store urine adequately results from bladder overactivity (involuntary contraction and/or decreased compliance), decreased outlet resistance, heightened or altered sensation, or a combination.

Bladder Overactivity

Overactivity of the bladder during filling/storage can be expressed as phasic involuntary contractions, as low compliance, or as a combination. Involuntary contractions are most commonly seen in association with neurologic disease or injury, bladder outlet obstruction, stress urinary incontinence (perhaps because of sudden entry of urine into the proximal urethra, eliciting a reflex contraction), or aging (probably related to neural degeneration) or

may be truly idiopathic. However, they may also be associated with increased afferent input related to inflammation or irritation of the bladder or urethral wall or an increased sensitivity (decreased threshold of activation to a normal amount of transmitter). Excitatory neurotransmitters may be released from the urothelium during filling/storage and activate afferent receptors/nerves, ultimately resulting, in some individuals, in involuntary contractions or altered (heightened) sensation: a premature sensation of distention or fullness, true urgency (a sudden compelling desire to void, which is difficult to defer), or pain. If an individual has urgency urinary incontinence, it can be assumed that an involuntary contraction (DO) has occurred. The symptom of urgency without incontinence suggests DO, but this is often not demonstrable on urodynamic study. Conversely, urodynamically demonstrable DO may not be associated with clinically troublesome filling/storage symptoms.

The possible pathophysiologies of the symptom syndrome “overactive bladder” (defined by the International Continence Society [ICS] as urgency with or without urge incontinence, usually with frequency and nocturia) can be summarized as (1) reduced suprapontine inhibition, (2) damaged axonal paths in the spinal cord, (3) damaged axonal paths in the periphery, (4) loss of peripheral inhibition, (5) enhancement of excitatory neurotransmission in the micturition reflex pathway, (6) increased LUT afferent input, and (7) idiopathic. Staskin (2001) and Mostwin and colleagues (2005) also hypothesized that decreased stimulation from the pelvic floor can contribute to phasic bladder overactivity. Decreased compliance during filling/storage may be secondary to neurologic injury or disease, usually at a sacral or infrasacral level, but may result from any process that impairs or destroys the viscoelastic or elastic properties of the bladder wall.

Filling/Storage Failure due to Altered Sensation

Bladder-related storage failure may also occur in the absence of overactivity because of increased afferent input from inflammation,

BOX 70-2 Expanded Functional Classification of Lower Urinary Tract Dysfunction

- I. Failure to store
 - A. Because of the bladder
 - 1. Overactivity
 - a. Involuntary contractions (detrusor overactivity)
 - (1) Neurologic disease, injury, or degeneration
 - (2) Bladder outlet obstruction
 - (3) Increased afferent input or sensitivity
 - (4) Inflammation

irritation, other causes of hypersensitivity, and pain. The causes may be chemical, psychological, or idiopathic. One classic example is termed *bladder pain syndrome* (also known as *interstitial cystitis*; see Chapter 14). Increased afferent activity can be responsible for true DO (an involuntary contraction), true urgency without DO, a premature feeling of fullness or distention without urgency or DO, or the sensation of pain during filling.

Outlet Underactivity

Decreased outlet resistance may result from any process that damages the innervation of structural elements of the smooth or striated sphincter, or both, or damages or impairs the support of the bladder outlet in women. This process may occur with neurologic disease or injury, surgical or other mechanical trauma, or aging. Classically, sphincteric incontinence in a woman was categorized into relatively discrete entities: (1) so-called *genuine stress incontinence* and (2) *intrinsic sphincter deficiency (ISD)*, originally described as “type III stress incontinence” (DeLancey, 1994; Mostwin et al, 2005; Koelbl et al, 2013) (see Chapters 69, 74, 82, and 84). *Genuine stress incontinence in women* was described as associated with hypermobility of the bladder outlet because of poor pelvic support and with an outlet that was competent at rest but lost its competence only during increases in intra-abdominal pressure. ISD described a nonfunctional or poorly functional bladder neck and proximal urethra at rest. The implication of classic ISD was that a surgical procedure designed to correct only urethral hypermobility would have a relatively high failure rate, as opposed to one designed to improve urethral coaptation and compression. The contemporary view is that most cases of effort-related incontinence in women involve varying proportions of

support-related factors and ISD. It is possible to have outlet-related incontinence that is due only to ISD but not due solely to hypermobility or poor support—some ISD must exist.

Stress or effort-related urinary incontinence is a symptom that arises primarily from **damage to muscles, nerves, or connective tissue, or a combination, within the pelvic floor** (DeLancey et al, 2002; Mostwin et al, 2005; Koelbl et al, 2013). Urethral support is important in women, the urethra normally being supported by the action of the levator ani muscles through their connection to the endopelvic fascia of the anterior vaginal wall. Damage to the connection between this fascia and this muscle, damage to the relevant nerve supply, or direct muscle damage can influence continence. Bladder neck function is likewise important, and loss of normal bladder neck closure can result in incontinence despite normal urethral support. Previously, the urethra was sometimes ignored as a factor contributing to continence in women, and the site of continence was thought to be exclusively the bladder neck. However, in approximately 50% of continent women, urine enters the urethra during increases in abdominal pressure. The continence point in these women (highest point of pressure transmission) is at the mid-urethra.

Urethral hypermobility implies weakness of the pelvic floor support structures. During increases in intra-abdominal pressure, there is descent of the bladder neck and proximal urethra. If the outlet opens concomitantly, stress urinary incontinence ensues. In the classic form of urethral hypermobility, there is rotational descent of the bladder neck and urethra. The urethra may also descend without rotation (it shortens and widens), or the posterior wall of the urethra may be pulled (sheared) open while the anterior wall remains fixed. However, urethral hypermobility is often present in women who are not incontinent, and the mere presence of urethral

hypermobility is insufficient to make a diagnosis of a sphincter abnormality unless urinary incontinence is also demonstrated. The “hammock hypothesis” of DeLancey (1994) proposes that for stress incontinence to occur with hypermobility, there must be a lack of stability of the suburethral supportive layer. This theory proposes that the effect of abdominal pressure increases on the normal bladder outlet, if the suburethral supportive layer is firm, is to compress the urethra rapidly and effectively. If the supportive suburethral layer is lax and/or movable, compression is not as effective. **Intrinsic sphincter dysfunction** denotes an intrinsic malfunction of the urethral sphincter mechanism itself. In its most overt form, it is characterized by a bladder neck that is open at rest and a low abdominal leak point pressure and urethral closure pressure (see Chapter 73) and is usually the result of prior surgery, trauma with scarring, or a neurologic lesion.

Urethral instability refers to the rare phenomenon of episodic decreases in outlet pressure unrelated to increases in bladder or abdominal pressure. Although rarely seemingly demonstrable, many authors believe that the decrease in urethral pressure usually represents simply the urethral component of what would otherwise be a bladder contraction/urethral relaxation in an individual whose bladder does not measurably contract, for either myogenic or neurogenic reasons. Little has appeared about this entity since the last edition of this text.

In theory at least, categories of outlet-related incontinence in men are similar to the categories in women. However, sphincteric incontinence in men is not associated with hypermobility of the bladder neck and proximal urethra but is similar to what is termed *intrinsic sphincter dysfunction* in women. There is essentially no information on the topic of urethral instability in men.

The treatment of filling/storage abnormalities is directed toward inhibiting bladder contractility, decreasing sensory output, mechanically increasing bladder capacity, or increasing outlet resistance, the last either continuously or just during increases in intra-abdominal pressure.

Emptying/Voiding Failure

Absolute or relative failure to empty the bladder results from decreased bladder contractility (a decrease in magnitude, coordination, or duration), increased outlet resistance, or a combination.

Bladder Underactivity

Absolute or relative failure of bladder contractility may result from temporary or permanent failure or impairment in one of the neuromuscular mechanisms necessary for initiating and maintaining a normal detrusor contraction. Inhibition of the voiding reflex in a neurologically normal individual may also occur; it may be by a reflex mechanism secondary to increased afferent input, especially from the pelvic and perineal areas, or may be psychogenic. **Non-neurogenic causes** also include impairment of bladder smooth muscle function, which may result from

overdistention, various centrally or peripherally acting drugs, severe infection, or fibrosis.

Outlet Overactivity or Obstruction

Pathologically increased outlet resistance is much more common in men than in women. Although it is most often secondary to anatomic obstruction, it may be secondary to a failure of relaxation or active contraction of the striated or smooth sphincter during bladder contraction (see Chapter 75). **Striated sphincter dyssynergia** is a common cause of functional (nonanatomic as opposed to fixed anatomic) obstruction in patients with neurologic disease or injury. Except for the true smooth sphincter contraction, which occurs in conjunction with autonomic hyperreflexia (see Chapter 75), true dyssynergia at the level of the bladder neck-proximal urethra is unusual. Incomplete opening of an anatomically normal bladder neck during voluntary or involuntary voiding is termed *bladder neck dysfunction* and is an uncommon entity found almost exclusively in young and middle-aged men (also sometimes known as *primary bladder neck obstruction* or *dysfunctional bladder neck*) (see Chapter 75). Common causes of **anatomic outlet obstruction in men** include prostatic enlargement, bladder neck contracture, and urethral stricture. A common cause of **outlet obstruction in women** is compression or fibrosis after surgery for sphincteric incontinence.

The treatment of emptying failure generally consists of maneuvers to increase intravesical/detrusor pressure, facilitate the micturition reflex, decrease outlet resistance, or a combination. If other means fail or are impractical, intermittent (or continuous) catheterization is an effective way to circumvent emptying failure.

CLASSIFICATION SYSTEMS

On the basis of the data obtained from the neurourologic evaluation, a given LUT dysfunction can be categorized in an ever-increasing number of descriptive systems. The **purpose of any classification system** should be to facilitate understanding and management and to avoid confusion among those who are concerned with the problem for which the system was designed. A good classification system should serve as **intellectual shorthand** and should convey, in a few key words or phrases, the essence of a clinical situation. An ideal system for all types of voiding dysfunction would include or imply several factors: (1) the conclusions reached from urodynamic testing, (2) expected clinical symptoms, and (3) approximate site and type of a neurologic lesion or lack of one. If the various categories accurately portray pathophysiology, treatment options should be obvious, and a treatment “menu” should be evident. **Most classification systems for voiding dysfunction were formulated primarily to describe dysfunction secondary to neurologic disease or injury. The ideal system should be applicable to all types of voiding dysfunction.** On the basis of the data obtained from the neurourologic evaluation, a given voiding dysfunction can be categorized in many descriptive systems. **No one system is perfect.** The major systems or types of systems in use are reviewed here with their advantages and applicability. Understanding the rationale and shortcomings of each system significantly improves one’s knowledge of LUT function and dysfunction.

Functional System

Classification of voiding dysfunction can be formulated on a simple functional basis, describing the dysfunction in terms of whether the deficit produced is primarily one of the filling/storage or the emptying/voiding phase of micturition (see Box 70-1) (Wein, 1981; Wein and Barrett, 1988). The genesis of such a system was proposed initially by Scott’s group (Quesada et al,

1968). This simple scheme assumes only that, whatever their differences, all “experts” would agree on the two-phase concept of micturition (filling/storage and emptying/voiding), on the simple overall mechanisms underlying the normality of each phase (see previous discussion), and on the possibilities for dysfunction.

The expansion of this concept to encompass all types of LUT dysfunction (see Box 70-2) and categorize urodynamic and video-urodynamic studies (see Table 70-1) has been previously discussed. In addition, one can easily classify all known treatments for voiding dysfunction under the broad categories of whether they facilitate filling/storage and emptying/voiding and whether they do so by an action primarily on the bladder or on one or more of the components of the bladder outlet (see Boxes 70-3 and 70-4).

Failure in either category generally is not absolute but more often is relative. Such a functional system can easily be “expanded” and made more complicated to include etiologic or specific urodynamic connotations (see Box 70-4). However, the simplified system is workable and avoids argument in complex situations in which the exact etiology or urodynamic mechanism for a voiding dysfunction cannot be agreed on.

Proper use of the functional system for a given voiding dysfunction requires a reasonably accurate notion of what the urodynamic data show. However, an exact diagnosis is not required for treatment. Some patients do not have only a discrete storage or emptying failure, and the existence of combination deficits must be recognized to use this system classification properly. For example, the “classic” T10 paraplegic patient after spinal shock generally exhibits a relative failure of storage because of involuntary bladder contraction and a relative failure to empty the bladder because of striated sphincter dyssynergia. With such a combination deficit, to use this classification system as a guide to treatment, one must assume that one of the deficits is primary and that significant improvement will result from its treatment alone or that the voiding dysfunction can be converted primarily to a disorder of either storage or emptying by means of nonsurgical or surgical therapy. The resultant deficit can then be treated or circumvented. Using this example, the combined deficit in a T10 paraplegic patient can be converted primarily to a storage failure by procedures directed at the dyssynergic striated sphincter; the resultant storage failure (secondary to involuntary contraction) can be circumvented (in a man) with an external collecting device. Alternatively, the deficit can be converted primarily to an emptying failure by pharmacologic or surgical measures designed to abolish or reduce the involuntary contraction, and the resultant emptying failure can be circumvented with clean intermittent catheterization. Other examples of combination deficits include impaired bladder contractility or overactivity with sphincter dysfunction, bladder outlet obstruction with DO, bladder outlet obstruction with sphincter malfunction, and detrusor filling/storage overactivity with impaired emptying contractility.

One advantage of this functional classification is that it allows the clinician the liberty of “playing” with the system to suit his or her own preferences without an alteration in the basic concept of “keep it simple but accurate and informative.” For instance, one could easily substitute the terms *overactive* or *oversensitive bladder* and *underactive outlet* for *because of the bladder* and *because of the outlet* under “Failure to Store” in Box 70-1. One could choose to categorize the bladder reasons for overactivity (see Box 70-2) further in terms of neurogenic, myogenic, or anatomic causes and subcategorize neurogenic further in terms of decreased inhibitory control, increased afferent activity, and increased sensitivity to efferent activity. The system is flexible.

The classification system proposed by the ICS (Box 70-5) is in essence an extension of a urodynamic classification system. The storage and voiding phases of micturition are described separately, and, within each phase, various designations are applied to describe bladder and urethral function (Abrams et al, 1988, 1992). Some of the definitions were changed by the standardization subcommittee of the ICS in 2002, and the relevant changes are indicated here (Abrams et al, 2002, 2003). Normal bladder function during

filling/storage implies no significant increases in detrusor pressure (stability). Overactive detrusor function indicates the presence of “involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked.” If the condition is caused by neurologic disease, the term *neurogenic detrusor overactivity* (previously, *detrusor hyperreflexia*) is applied. If not, the term *idiopathic detrusor overactivity* (previously, *detrusor instability*) is applied. Bladder sensation can be categorized only in qualitative terms as indicated. Bladder capacity and compliance (Δ volume/ Δ pressure) are cystometric measurements. Bladder capacity can refer to cystometric capacity, maximum cystometric capacity, or maximum anesthetic cystometric capacity (Abrams et al, 2002). Normal urethral function during filling/storage indicates a positive urethral closure pressure (urethral pressure minus bladder pressure) even with increases in intra-abdominal pressure, although it may be overcome by DO. Incompetent urethral function during filling/storage implies urine leakage in the absence of a detrusor contraction. This leakage may be due to genuine stress incontinence, intrinsic sphincter dysfunction, a combination, or an involuntary decrease in urethral pressure in the absence of detrusor contraction.

During the voiding/emptying phase of micturition, normal detrusor activity implies voiding by a voluntarily initiated sustained contraction that leads to complete bladder emptying within a normal time span. An underactive detrusor defines a contraction of inadequate magnitude or duration, or both, to empty the bladder within a normal time span. An *accontractile detrusor* is one that cannot be demonstrated to contract during urodynamic testing. *Areflexia* is defined as *accontractility* secondary to an abnormality of neural control, implying the complete absence of centrally

coordinated contraction. **Normal urethral function** during voiding indicates a urethra that opens and is continuously relaxed to allow bladder emptying at a normal pressure. **Abnormal urethral function during voiding** may be due to either mechanical obstruction or urethral overactivity. **Dysfunctional voiding** describes an intermittent or fluctuating flow rate secondary to involuntary intermittent contractions of the periurethral striated muscle in neurologically normal individuals. **Detrusor sphincter dyssynergia** defines a detrusor contraction concurrent with an involuntary contraction of the urethral or periurethral striated muscle, or both. **Nonrelaxing urethral sphincter obstruction** usually occurs in individuals with a neurologic lesion and is characterized by a nonrelaxing obstructing urethra resulting in reduced urine flow.

LUT dysfunction in a patient with classic T10-level paraplegia after spinal shock has passed would be classified in the ICS system as follows:

- Storage phase—overactive neurogenic detrusor function, absent sensation, low capacity, normal compliance, normal urethral closure function
- Voiding phase—overactive obstructive urethral function, overactive detrusor function

The micturition dysfunction of a patient with stroke and urgency incontinence would most likely be classified during storage as overactive neurogenic detrusor function, normal sensation, low capacity, normal compliance, and normal urethral closure function. During voiding, the dysfunction would be classified as normal detrusor activity and normal urethral function, assuming that no anatomic obstruction existed.

Urodynamic Classification

As urodynamic techniques have become more accepted and sophisticated, systems of classification have evolved solely on the basis of objective urodynamic data (Box 70-6). Among the first to popularize this concept were Krane and Siroky (1984). When exact urodynamic classification is possible, such a system can provide an exact description of the voiding dysfunction that occurs. If a normal or hyperreflexic (overactive) detrusor exists with coordinated smooth and striated sphincter function and without anatomic obstruction, normal bladder emptying should occur. **Detrusor hyperreflexia** (now termed *neurogenic detrusor overactivity* in ICS parlance) is most commonly associated with neurologic lesions above the sacral spinal cord. **Striated sphincter dyssynergia** is most commonly seen after complete suprasacral spinal cord injury, following the period of spinal shock. **Smooth sphincter dyssynergia** is seen most classically in autonomic hyperreflexia (see Chapter 75) when it is characteristically associated with DO and striated sphincter dyssynergia. **Detrusor areflexia** (this category includes acontractile and areflexic

bladder) may be secondary to bladder muscle decompensation or to various other conditions that produce inhibition at the level of the brainstem micturition center, the sacral spinal cord, bladder ganglia, or bladder smooth muscle. Patients with a voiding dysfunction secondary to detrusor areflexia generally attempt bladder emptying by abdominal straining, and their continence status and the efficiency of their emptying efforts are determined by the status of their smooth and striated sphincter mechanisms.

This classification system is easiest to use when detrusor hyperreflexia (overactivity) or normoreflexia exists. A patient with typical T10-level paraplegia after spinal shock exhibits detrusor hyperreflexia, smooth sphincter synergy, and striated sphincter dyssynergia. When a voluntary or a hyperreflexic contraction cannot be elicited, the system is more difficult to use because it is not appropriate to speak of true sphincter dyssynergia in the absence of an opposing bladder contraction. There are many variations and extensions of such a system. **Such systems can work well only when total urodynamic agreement exists among classifiers. There are many dysfunctions that do not fit neatly into a urodynamic classification system that is agreed on by all experts. Compliance is not mentioned in this particular version, nor is sensation or the concept of deficient, but not absent, detrusor contractile function.** As sophisticated urodynamic technology and understanding improve, this type of classification system may be more commonly used. The ICS system (see previous discussion) is in reality a logical and more complete extension of such a system.

Lapides's Classification

Lapides (1970) contributed significantly to the classification and care of patients with neuropathic voiding dysfunction by slightly modifying and popularizing a system originally proposed by McLellan (1939) (Box 70-7). Lapides's classification differs from that of McLellan in only one respect, and that is the division of the group of "atonic neurogenic bladder" into sensory neurogenic and motor neurogenic bladder. This is a familiar system to urologists and nonurologists because it describes in recognizable shorthand the clinical and cystometric conditions of many types of neurogenic voiding dysfunction.

A **sensory neurogenic bladder** results from disease that selectively interrupts the sensory fibers between the bladder and the spinal cord or the afferent tracts to the brain. **Diabetes mellitus, tabes dorsalis, and pernicious anemia** are the diseases most responsible. The first clinical changes are described as impaired sensation of bladder distention. Unless voiding is initiated on a timed basis, varying degrees of bladder overdistention can result with hypotonicity. If bladder decompensation occurs, significant amounts of residual urine result, and at that time the cystometric curve generally demonstrates a large-capacity bladder with a flat, high-compliance, low-pressure filling curve.

A **motor paralytic bladder** results from disease processes that destroy the parasympathetic motor innervation of the bladder. **Extensive pelvic surgery or trauma** may produce this. **Herpes zoster** has been listed as a cause as well, but more recent evidence suggests that the voiding dysfunction seen with herpes may be related more to a problem with afferent input (see Chapter 75). The early symptoms of a motor paralytic bladder may vary from painful urinary retention to only a relative inability to initiate and maintain normal micturition. Early cystometric filling is normal but without

Reflex neurogenic bladder
Autonomous neurogenic bladder

a voluntary bladder contraction at capacity. Chronic overdistention and decompensation may occur, resulting in a large-capacity bladder with a flat, low-pressure filling curve; a large amount of residual urine may result.

An **uninhibited neurogenic bladder** was described originally as resulting from injury or disease to the “corticoregulatory tract.” The sacral spinal cord was presumed to be the micturition reflex center, and this corticoregulatory tract was believed normally to exert an inhibitory influence on the sacral micturition reflex center. A destructive lesion in this tract would then result in overfacilitation of the micturition reflex. **Cerebrovascular accident, brain or spinal cord tumor, Parkinson disease, and demyelinating disease** were listed as the most common causes in this category. The voiding dysfunction is most often characterized symptomatically by frequency, urgency, and urge incontinence and urodynamically by normal sensation with involuntary contraction at low filling volumes. Residual urine is characteristically low unless anatomic outlet obstruction or true smooth or striated sphincter dyssynergia occurs. The patient generally can initiate a bladder contraction voluntarily but is often unable to do so during cystometry because sufficient urine storage cannot occur before involuntary contraction is stimulated.

Reflex neurogenic bladder refers to the post-spinal shock condition that exists after complete interruption of the sensory and motor pathways between the sacral spinal cord and the brainstem. Most commonly, this condition occurs in **traumatic spinal cord injury and transverse myelitis**, but it may occur with **extensive demyelinating disease or any process that produces significant suprasacral (cord) spinal cord destruction**. Typically, there is no bladder sensation, and there is inability to initiate voluntary micturition. Incontinence without sensation generally results from low-volume involuntary contraction. Striated sphincter dyssynergia is the rule. This type of lesion is essentially equivalent to a complete upper motor neuron (UMN) lesion in the Bors-Comarr system (see later).

An **autonomous neurogenic bladder** results from complete motor and sensory separation of the bladder from the sacral spinal cord. This condition may be caused by **any disease that destroys the sacral cord or causes extensive damage to the sacral roots or pelvic nerves**. There is inability to initiate micturition voluntarily, no bladder reflex activity, and no specific bladder sensation. This type of bladder is equivalent to a complete lower motor neuron (LMN) lesion in the Bors-Comarr system and is the type of dysfunction seen in patients with spinal shock. The characteristic cystometric pattern is initially similar to the late stages of the motor or sensory paralytic bladder, with a marked shift to the right of the cystometric filling curve and a large bladder capacity at low intravesical pressure. However, decreased compliance may develop, secondary either to chronic inflammatory change or to the effects of denervation/decentralization with secondary neuromorphologic and neuropharmacologic reorganizational changes. Emptying capacity may vary widely, depending on the ability of the patient to increase intravesical pressure and on the resistance offered during this increase by the smooth and striated sphincters.

These classic categories in their usual settings are generally understood and remembered, and this is why this system provides an excellent framework for teaching some fundamentals of neurogenic voiding dysfunction to students and nonurologists. However, **many patients do not fit exactly into one or another category**. Gradations of sensory, motor, and mixed lesions occur, and the patterns produced after different types of peripheral denervation/defunctionalization may vary widely from the patterns that are classically described. **The system is applicable only to neuropathic dysfunction.**

Bors and Comarr (1971) made a remarkable contribution by logically deducing a classification system from clinical observation of their patients with traumatic spinal cord injury (**Box 70-8**). This system, primarily of historical interest at present, applies only to patients with neurologic dysfunction and considers three factors: (1) the anatomic localization of the lesion, (2) the neurologic completeness or incompleteness of the lesion, and (3) whether

LUT function is *balanced* or *unbalanced*. The last terms are based solely on the percentage of residual urine relative to bladder capacity. **Unbalanced** signifies the presence of greater than 20% residual urine in a patient with a UMN lesion or 10% in a patient with an LMN lesion. This relative residual urine volume was ideally meant to imply coordination (synergy) or dyssynergia between the smooth and the striated sphincters of the outlet and the bladder during bladder contraction or during attempted micturition by abdominal straining or the Credé maneuver. The determination of the completeness of the lesion is made on the basis of a thorough neurologic examination.

The system erroneously assumes that the sacral spinal cord is the primary reflex center for micturition. LMN implies collectively the preganglionic and postganglionic parasympathetic autonomic fibers that innervate the bladder and outlet and originate as preganglionic fibers in the sacral spinal cord. The term is used in an analogy to efferent somatic nerve fibers such as those of the pudendal nerve, which originate in the same sacral cord segment but terminate directly on pelvic floor striated musculature without the interposition of ganglia. UMN is used in a similar analogy to the somatic nervous system to describe the descending autonomic pathways above the sacral spinal cord (the origin of the motor efferent supply to the bladder).

In this system, **UMN bladder** refers to the pattern of micturition that results from an injury to the suprasacral spinal cord after the period of spinal shock has passed, assuming that the sacral spinal cord and the sacral nerve roots are intact and that the pelvic and pudendal nerve reflexes are intact. **LMN bladder** refers to the pattern resulting if the sacral spinal cord or sacral roots are damaged and the reflex pattern through the autonomic and somatic nerves that emanate from these segments is absent. This system implies that if skeletal muscle spasticity exists below the level of the lesion, the lesion is above the sacral spinal cord and is by definition a UMN lesion. This type of lesion is characterized by involuntary bladder contraction during filling. If flaccidity of the skeletal musculature below the level of a lesion exists, an LMN lesion is assumed to be present, implying that detrusor areflexia is present. Exceptions occur and are classified in a “**mixed lesion group**” characterized either by involuntary bladder contraction with a flaccid paralysis below the level of the lesion or by detrusor areflexia with spasticity

or normal skeletal muscle tone neurologically below the lesion level.

The use of this system is illustrated as follows. A “**UMN lesion, complete, imbalanced**” implies a neurologically complete lesion above the level of the sacral spinal cord that results in skeletal muscle spasticity below the level of the injury. Involuntary bladder contraction occurs during filling, but a residual urine volume of greater than 20% of the bladder capacity is left after bladder contraction, implying obstruction in the area of the bladder outlet during the involuntary detrusor contraction. This obstruction is generally due to striated sphincter dyssynergia, typically occurring in patients who are paraplegic or quadriplegic with lesions between the cervical and the sacral spinal cord. Smooth sphincter dyssynergia may be seen as well in patients with lesions above the level of T6, usually associated with autonomic hyperreflexia (see Chapter 75). An “**LMN lesion, complete, imbalanced**” implies a neurologically complete lesion at the level of the sacral spinal cord or of the sacral roots, resulting in skeletal muscle flaccidity below that level. Detrusor areflexia results, and whatever measures the patient may use to increase intravesical pressure during attempted voiding are insufficient to decrease residual urine to less than 10% of bladder capacity.

This classification system applies best to spinal cord injury patients with complete neurologic lesions after spinal shock has passed. It is difficult to apply to patients with multicentric neurologic disease and cannot be used at all for patients with non-neurologic disease. The system fails to reconcile the clinical and urodynamic variability exhibited by patients who, by neurologic examination alone, seem to have similar lesions. The period of spinal shock that immediately follows severe cord injury is generally associated with bladder areflexia, whatever the status of the sacral somatic reflexes. Temporary or permanent changes in bladder or outlet activity during filling/storage and emptying/voiding may occur as a result of numerous factors, such as chronic overdistention, infection, and reinnervation or reorganization of neural pathways after injury or disease; such changes make it impossible to predict LUT activity accurately solely on the basis of the level of the neurologic lesion. Finally, although the terms *balanced* and *imbalanced* are helpful, in that they describe the presence or absence of a certain relative percentage of residual urine, they do not imply the true functional significance of a lesion, which depends on the potential for damage to the lower or upper urinary tracts and on the social and vocational disability that results.

Hald-Bradley Classification

Hald and Bradley (1982) described what they termed a simple neurotopographic classification (Box 70-9). The system is of historical interest only. A **suprasacral lesion** is characterized by synergy between detrusor contraction and the smooth and striated sphincters, but defective inhibition of the voiding reflex exists. Involuntary bladder contraction generally occurs, and sensation is usually preserved. However, depending on the site of the lesion, detrusor areflexia and defective sensation may be seen. A **suprasacral spinal lesion** is roughly equivalent to what is described as a UMN lesion in the Bors-Comarr classification. An **infrasacral lesion** is roughly equivalent to an LMN lesion. **Peripheral autonomic neuropathy** is most frequently encountered in diabetic patients and is character-

ized by deficient bladder sensation, gradually increasing residual urine, and ultimate decompensation, with loss of detrusor contractility. A **muscular lesion** can involve the detrusor itself, the smooth sphincter, or any portion, or all, of the striated sphincter. The resultant dysfunction depends on which structure is affected. Detrusor dysfunction is the most common and generally results from decompensation following long-standing bladder outlet obstruction. In my opinion, this system is as confusing as the word neurotopographic and adds little to the understanding of LUT dysfunction.

Bradley Classification

Bradley’s “**loop system**” of classification is a primarily neurologic system based on his conceptualization of central nervous system control of the LUT that identifies four neurologic “loops” (Hald and Bradley, 1982). Dysfunctions are classified according to the loop affected. Occasional reference is made to this system, primarily by nonurologists.

Loop 1 consists of neuronal connections between the cerebral cortex and the pontine mesencephalic micturition center; this coordinates voluntary control of the detrusor reflex. **Loop 1 lesions** are seen in conditions such as **brain tumor, cerebrovascular accident or disease, and cerebral atrophy with dementia**. The final result is characteristically **involuntary bladder contractions**.

Loop 2 includes the intraspinal pathway of detrusor muscle afferents to the brainstem micturition center and the motor impulses from this center to the sacral spinal cord. Loop 2 is thought to coordinate and provide for a detrusor reflex of adequate temporal duration to allow complete voiding. Partial interruption by spinal cord injury results in a detrusor reflex of low threshold and in poor emptying with residual urine. **Spinal cord transection of loop 2 acutely produces detrusor areflexia and urinary retention—spinal shock. After this has passed, involuntary bladder contractions result.**

Loop 3 consists of the peripheral detrusor afferent axons and their pathways in the spinal cord; these terminate by synapsing on pudendal motor neurons that ultimately innervate periurethral striated muscle. Loop 3 was thought to provide a neurologic substrate for coordinated reciprocal action of the bladder and striated sphincter. **Loop 3 dysfunction could be responsible for detrusor striated dyssynergia or involuntary sphincter relaxation.**

Loop 4 consists of two components. Loop 4A is the suprasacral afferent and efferent innervation of the pudendal motor neurons to the periurethral striated musculature. Loop 4B consists of afferent fibers from the periurethral striated musculature that synapse on pudendal motor neurons in Onuf nucleus—the segmental innervation of the periurethral striated muscle. Bradley conceptualized that, in contrast to the stimulation of detrusor afferent fibers, which produced inhibitory postsynaptic potentials in pudendal motor neurons through loop 3, pudendal nerve afferents produced excitatory postsynaptic potentials in those motor neurons through loop 4B. These provided for contraction of the periurethral striated muscle during bladder filling and urine storage. The related sensory impulses arise from muscle spindles and tendon organs in the pelvic floor musculature. **Loop 4 provides for volitional control of the striated sphincter.** Abnormalities of the suprasacral portion result in abnormal responses of the pudendal motor neurons to bladder filling and emptying, manifested as detrusor striated sphincter dyssynergia and/or loss of the ability to contract the striated sphincter voluntarily.

The Bradley system is sophisticated and reflects the ingenuity and neurophysiologic expertise of its originator, himself a neurologist. For neurologists, this method may be an excellent way to conceptualize the neurophysiology involved, assuming that there is agreement on the existence and significance of all four loops—a big assumption. Most urologists find this system difficult to use for many types of neurogenic LUT dysfunction and not applicable to non-neurogenic LUT dysfunction. Urodynamically, it may be extremely difficult to test the intactness of each loop system, and multicentric and partial lesions are difficult to describe.

BOX 70-9 Hald-Bradley Classification

- Suprasacral lesion
- Suprasacral spinal lesion
- Infrasacral lesion
- Peripheral autonomic neuropathy
- Muscular lesion

Definition and Impact of Pelvic Floor Disorders

Diagnostic Evaluation

Management

Conclusion

DEFINITION AND IMPACT OF PELVIC FLOOR DISORDERS

Pelvic floor disorders (PFDs), which include urinary incontinence, fecal incontinence, and pelvic organ prolapse (POP), pose a prevalent worldwide health concern. (For the purposes of this chapter, *incontinence* will refer to urinary leakage unless otherwise specified.) A detailed overview of the epidemiology and pathophysiology of pelvic floor disorders appears in Chapter 74.

The impact of PFDs is far-reaching, carrying a significant potential to affect patient quality of life (QoL), notwithstanding the psychological burden they produce. Additionally, incontinence creates a tremendous cost to the individual and to society. [Hu and colleagues \(2004\)](#) estimated that the evaluation and management of incontinence and productivity lost as a result of the condition resulted in a \$19.5 billion (year 2000 dollars) cost to society, although sensitivity analysis suggested a potential cost range of \$9.32 to \$28 billion. Contemporary numbers might predictably be higher, although Hu's most recent analysis demonstrated a 26% cost decrease compared to their 1995 report, which estimated \$26.29 billion. The decrease was speculated to be due to various factors, including decreased hospital stays and adjusted methods of assessing nursing home stays, routine care product use, and prevalence data. Other reports have demonstrated that medical expenditures for incontinence in the female Medicare population nearly doubled between 1992 and 1998, the result primarily of increased outpatient expenditure from 9.1% to 27.3% of total Medicare costs in approximately the same timeframe ([Thom et al, 2005](#); [Anger et al, 2006](#)). Contemporary estimates of the economic burden imparted by PFDs range widely. [Chong and associates \(2011\)](#) reported an annual cost of over \$12 billion for stress urinary incontinence (SUI). [Milsom and colleagues \(2014\)](#) reported a cost of \$66 billion per year for urinary urgency incontinence in 2007, and [Ganz and coworkers \(2010\)](#) projected a total annual cost of \$76.2 billion in 2015 and \$82.6 billion in 2020. [Sung and colleagues \(2010\)](#) reported a cost of \$412 million, including deductibles and copayments for PFDs, in 2005 and 2006.

[Wu and colleagues \(2009\)](#) used U.S. Census Bureau population projections to forecast the change in PFD prevalence in women between 2010 and 2050. The current estimate of 28.1 million women with at least one PFD in 2010 is projected to increase substantially to 43.8 million in 2050. Accordingly, the same group predicted an increase in surgical treatment of SUI and POP during the same period of 47.2% and 48.2%, respectively ([Wu et al, 2009](#)).

As a result of increasing awareness of the societal impact of PFDs in addition to the growing emphasis on maximizing QoL in our aging population, tremendous research efforts are under way to improve our understanding of the pathophysiology of

these disorders, thereby improving both diagnostic and therapeutic techniques. The importance of evidence-based medicine and meticulous follow-up of patients is driving improvement in the science on which advancements in this subspecialty of urology are being made.

DIAGNOSTIC EVALUATION

General Considerations

A recent upsurge in research efforts has resulted in the emergence of new diagnostic and therapeutic techniques to address PFDs. As QoL impact has become a focus, much of current research efforts include detailed QoL assessment and attempts to quantify and assess the relationship between PFDs and their effects on QoL. Correlating the bother caused by a given PFD with the risk of available therapies is an important consideration. The purpose of evaluation of patients with urinary incontinence includes documentation and characterization of the incontinence, consideration of the differential diagnosis, prognostication and facilitation of treatment selection ([Dmochowski et al, 2010](#)). Additionally, proper evaluation helps assess symptom bother and establish a patient's expectations of potential outcomes.

The type of incontinence affecting an individual must be defined and quantified to guide proper treatment planning. Transient or unrelated conditions that can cause leakage should be identified before proceeding with definitive therapy. [Box 71-1](#) contains a mnemonic of transient causes of incontinence ([Resnick, 1984](#)). [Table 71-1](#) lists current International Urogynecological Association (IUGA)/International Continence Society (ICS) nomenclature regarding urinary incontinence symptoms ([Abrams et al, 2002, 2009b](#); [Haylen et al, 2010](#)). The terminology continues to adjust to reflect the evolving understanding of the condition. The importance of this flexibility has been realized and acknowledged by leaders in the subspecialty of pelvic floor medicine ([Chapple, 2009](#)). Accordingly, the IUGA/ICS terminology has been updated since its inception and most recently has been expanded to include not only terminology for lower urinary tract (LUT) function and urodynamics (UDS) but also POP, LUT pain, sexual dysfunction, anorectal dysfunction, and pelvic imaging ([Haylen et al, 2010](#)).

The classification of POP is categorized according to the affected compartment. Simply put, anterior compartment prolapse (cystocele) generally involves descent of the bladder toward the vaginal lumen, posterior prolapse (rectocele) involves the rectum compressing the posterior vaginal wall into the vagina, and apical prolapse is associated with descent of the uterus (uterine procidentia) and/or the bowel (enterocele) at the top of the vagina. Several grading systems exist to quantify the severity of POP and are discussed later and illustrated in [Figure 71-1](#).

BOX 71-1 Causes of Transient Incontinence (DIAPPERS)

- Delerium
- Infection (urinary tract infection)
- Atrophic vaginitis/urethritis
- Psychological (e.g., severe depression, neurosis)
- Pharmacologic
- Excess urine production
- Restricted mobility
- Stool impaction

Regarding incontinence specifically, the substantiation of a proper diagnosis requires direct observation of urinary leakage by the clinician (Nitti and Blaivas, 2007). It is the belief of many experts that no patient should undergo invasive or irreversible therapies without definitive establishment of the cause of their incontinence and demonstration of leakage in the specific case of SUI. Complete and extensive evaluation can facilitate accurate diagnosis of PFDs to promote optimal treatment planning and counseling of patients.

History

A careful history should always be obtained from the patient. However, several studies have indicated that patient history alone

TABLE 71-1 Standard International Urogynecological Association/International Continence Society Terminology of Urinary Incontinence Symptoms

TERMINOLOGY	DESCRIPTION
Urinary incontinence	Complaint of any involuntary leakage of urine
Stress urinary incontinence	Complaint of involuntary leakage on effort or exertion or on sneezing or coughing
Urgency	Complaint of a sudden compelling desire to pass urine, which is difficult to defer
Urgency incontinence	Complaint of involuntary leakage accompanied by or immediately preceded by urgency
Postural incontinence	Complaint of voluntary loss of urine associated with change of body position (e.g., rising from a seated or lying position)
Nocturnal enuresis	Complaint of involuntary loss of urine that occurs during sleep
Mixed incontinence	Complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing
Continuous urinary incontinence	Complaint of continuous leakage
Insensible incontinence	Complaint of urinary incontinence in which the woman is unaware of how it occurred
Coital incontinence	Complaint of involuntary loss of urine with coitus

Data from Abrams P, Cardozo L, Fall M, et al. The standardisation of terminology of lower urinary tract function: report from the Standardisation Sub-Committee of the International Continence Society. *Neurourol Urodyn* 2002;21:167–78.

The clinical evaluation of pelvic floor dysfunction. *Obstet Gynecol Clin North Am* 1998;25:783–804.)

KEY POINTS: GENERAL CONSIDERATIONS

- PFDs are a prevalent worldwide health concern.
- Careful history and physical examination are integral in the proper evaluation of patients with PFDs.
- Supplementary evaluation including urinalysis (UA), post-void residual (PVR), UDS, endoscopy, and radiologic imaging can be helpful in arriving at a complete and accurate diagnosis.
- A variety of surgical and nonsurgical treatment options are available for treatment of urinary incontinence and POP.

is not completely accurate as the sole determinant of incontinence type (Summitt et al, 1992; Jensen et al, 1994). Bates and associates (1973) are credited with the dictum, “The bladder is an unreliable witness,” which has been corroborated by many investigators in various forms. Accordingly, all available information, including that obtained by supplementary examinations, should be integrated into the diagnosis.

History of Present Illness

A thorough history is imperative in the evaluation of incontinence. Several queries should be included in a continence and pelvic floor history to best portray the patient’s symptoms (Holroyd-Leduc et al, 2008). The incontinence first should be characterized subjectively. Does the leakage occur: With physical activity? With a sense of urgency? Without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? Second, the leakage should be quantified if possible. Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved based on the number of pads used per day or the frequency of clothing changes because of urinary leakage. In the setting of research or an academic practice, more stringent and objective measures such as pad weight testing are often used (see Supplemental Evaluation). Third, the voiding pattern should be defined. What is the frequency of urination during the day? During the night? Are there any obstructive symptoms? Does the patient have to wait for the stream to start (hesitancy)? Does the patient feel as though the bladder has emptied completely? Is the stream strong or does it “trickle”? Does the stream fluctuate during the void? Is it necessary to push or strain or change posture to void or empty the bladder? Fourth, establishment of the duration of symptoms and any inciting events that contributed to the onset of leakage is important. Did the leakage follow a pregnancy or a vaginal delivery? How long ago? Did the leakage start after a strain, a fall, or trauma? Has the patient undergone pelvic or back surgery? In males, has there been prostate or urethral surgery for benign or malignant disease? Has there been LUT instrumentation? Are there any accompanying neurologic symptoms, such as numbness or tingling in the extremities, blurry/double vision, balance or coordination changes, or tremor? It is helpful to determine the impact that the leakage has on the patient’s daily life and activities. Does the incontinence limit the individual’s activity? Has he or she made lifestyle changes because of the threat of leakage? Finally, the American Urological Association (AUA) guidelines emphasize the importance of establishing patient expectation of treatment and an understanding of the balance between the benefits and risks/burden of available treatment options (Dmochowski et al, 2010).

Regarding pelvic prolapse specifically, important questions focus on whether the patient is aware of any prolapse and what, if any, symptomatology and bother the prolapse may be causing. Does the patient feel that anything is falling down out of place in the vagina? Does she need to reduce the prolapse for comfort? Or to empty her bladder completely? Or to facilitate evacuation of her bowels?

Past Medical and Surgical History

Past medical and surgical histories are vital to the assessment of incontinence insofar as medical conditions and surgeries can affect urinary tract function. Childhood and adult urologic history should be obtained, as should a neurologic history. Neurologic conditions such as Parkinson disease, multiple sclerosis, stroke, spinal cord injury, back surgery, and myelodysplasia can have a considerable impact on LUT function. Medical diagnoses, such as diabetes mellitus and dementia, can affect continence. Similarly, a history of radiation therapy or neurologic or urologic trauma can affect LUT function, specifically with regard to outlet resistance and/or bladder contractility, stability, and compliance. Although outlet resistance may be compromised by trauma or LUT surgery, urethral strictures related to trauma or neurologic dysfunction that abnormally increase outlet resistance during voiding can cause obstruction and secondary symptoms related to the obstruction.

In women, the gynecologic and obstetric history, including gravity, parity, and hormonal status is important. Determination of whether the patient is premenopausal, perimenopausal, or postmenopausal and whether she has used any exogenous hormones such as oral contraceptives or local or systemic hormone replacement therapy can be helpful in her overall assessment. As mentioned previously, although beneficial effects of local hormone replacement therapy are well-established, there have been reports that exogenous systemic hormone therapy can actually increase the risk for SUI (Townsend et al, 2009; Cody et al, 2012).

Clearly, previous pelvic surgery can affect LUT function. Anti-incontinence surgery, POP repair, and hysterectomy can contribute to a variety of urinary symptoms in women. Similarly, a history of prostate surgery can give rise to voiding or leakage complaints in men. Abdominoperineal resection can result in neurologic injury that can affect the function of either the bladder or the sphincter (Petrelli et al, 1993), and back surgery can cause a variety of symptoms depending on the level affected.

Medications

An accurate assessment of medications is critical, particularly in the elderly patient population in whom polypharmacy is common. Many agents can affect urine production, LUT function, and mental status, all of which can have an impact on continence. Special attention should be focused on agents that can affect bladder/sphincteric function. Table 71-2 categorizes some commonly used classes of medications by mechanism of action and potential effect on the LUT.

TABLE 71-2 Pharmacologic Agents That Can Affect the Lower Urinary Tract

PHARMACOLOGIC EFFECTS	POTENTIAL EFFECTS ON URINARY TRACT
Sympathomimetics	Can increase outlet resistance and exacerbate obstructive symptoms/overactive bladder symptoms Can decrease detrusor contractility and precipitate retention
Sympatholytics	Can decrease outlet resistance and exacerbate stress incontinence
Anticholinergics	Can contribute to urinary retention, particularly in patients with outlet obstruction
Diuretics	Do not affect bladder directly, but because of increased urine production, can aggravate incontinence problems

Other

Because **genetics** can influence connective tissue integrity, it stands to reason that there may be a potential hereditary role in continence and POP (Twiss et al, 2007b). Therefore inquiry about family history of POP may be helpful. Additionally, a thorough review of systems may reveal symptoms that suggest other conditions that could have an impact on pelvic floor function.

Male incontinence, also a very prevalent health issue, should be assessed in much the same way as female incontinence, although specific consideration of the impact of the anatomy specific to the male should be considered. **Benign prostatic hyperplasia**, the evaluation of which is covered in detail in Chapter 104, can cause secondary urgency and urgency incontinence in addition to more “typical” obstructive symptoms, such as a decreased force of stream, urinary hesitancy, intermittency, and incomplete bladder emptying. **Prostate surgery for benign or malignant disease** can contribute to SUI. With this in mind, full assessment of male LUT symptoms (LUTS) should be performed to facilitate proper treatment planning.

KEY POINTS: HISTORY

- A thorough history is essential in the diagnostic evaluation of patients with PFDs.
- Queries specific to the character, severity, duration, and quantity of incontinence and other symptoms related to pelvic floor function should be performed.
- Attention should be paid to the impact of PFD symptoms on QoL.
- When appropriate, the clinician should present questions specific to the female with potential POP and the male with potential prostate issues.
- Queries regarding past medical and surgical history, obstetric and gynecologic history, radiation therapy, trauma, and medications may provide important information.

Physical Examination

The general appearance of a patient, including details such as age, gait, stature, and fragility, can provide important information regarding performance status, neurologic status, and other factors that may direct proper treatment planning. Similarly, an abdominal examination evaluating for incisions, hernias, organomegaly or bladder distention, and habitus is important, particularly if any abdominal surgery may be considered.

Per Medicare coding guidelines (Centers for Medicare and Medicaid Services, 1997), a female pelvic examination includes at least 7 of the 11 bulleted items listed in Box 71-2. The external genitalia should be evaluated with regard to general appearance, estrogen status, lesions, and labial size, and adhesions. Estrogen status can be evaluated based on the presence or absence of a urethral caruncle, urethral prolapse, and/or labial adhesions, all of which, if present, may indicate estrogen deficiency. Likewise, attention to the overall tissue appearance and color is important. Hormonally deficient vaginal tissue has a pale, flat, dry appearance with no rugae, as opposed to the healthy, pink rugated tissue of well-estrogenized tissue.

Urethral position and mobility should be assessed at rest and with straining and coughing. The **Q-tip test** was developed to objectify the evaluation of urethral mobility (Bergman and Bhatia, 1987; Walters and Diaz, 1987). The discomfort caused to the patient during insertion of the Q-tip can be minimized with the use of intraurethral lidocaine jelly. With the patient in the lithotomy position, a Q-tip is inserted into bladder through the urethra and the angle that the Q-tip moves from horizontal to its final position with straining is measured. Hypermobility is defined as a Q-tip angle of more than 30 degrees from horizontal.

Connective tissue support of the pelvis and the pelvic viscera was described by DeLancey in three levels. Levels I, II, and III represent

BOX 71-2 Components of a Focused Pelvic Examination

- Inspection and palpation of breasts (e.g., masses or lumps, tenderness, symmetry, nipple discharge)
- Digital rectal examination, including sphincter tone, presence of hemorrhoids, rectal masses
- Pelvic examination (with or without specimen collection for smears and cultures), including:
 - External genitalia (e.g., general appearance, hair distribution, lesions)
 - Urethral meatus (e.g., size, location, lesions, prolapse)
 - Urethra (e.g., masses, tenderness, scarring)
 - Bladder (e.g., fullness, masses, tenderness)
 - Vagina (e.g., general appearance, estrogen effect, discharge, lesions, pelvic support, cystocele, rectocele)
 - Cervix (e.g., general appearance, lesions, discharge)
 - Uterus (e.g., size, contour, positions, mobility, tenderness, consistency, descent or support)
 - Adnexa/parametria (e.g., masses, tenderness, organomegaly, nodularity)
 - Anus and perineum

At the time of this writing, 7 of 11 bullet points listed above are required to be considered a complete female genitourinary examination. However, other organ systems/body areas not limited to the genitourinary system may be included in a report to accomplish the requirements of various levels of examination.

Data from Centers for Medicare and Medicaid Services. Single organ system examination: genitourinary—1997 Documentation Guidelines for Evaluation and Management (E/M) Services, jointly approved by the American Medical Association and HCFA with revisions. Baltimore, November 1997.

the proximal, middle, and distal vaginal support, respectively, in this classification system that is now used worldwide. Level I involves the uterosacral and cardinal ligaments and supports the vaginal vault; level II supports the mid-vagina via attachment of the anterior and posterior endopelvic fascia to the lateral pelvic side walls; and level III support depends on the fusion of the endopelvic fascia to the pubic symphysis and perineal body (DeLancey, 1992). Assessment of prolapse ideally should be performed in both the lithotomy and standing positions, the latter facilitated by having the patient stand with one foot elevated on a short stool. Each compartment—the anterior, posterior, and apical (uterus/cervix or vaginal cuff)—should be evaluated methodically and the perineal body assessed for laxity. A complete systematic examination is performed using two posterior blades of a split Grave speculum with and without straining. First, one blade is used to retract the posterior wall to facilitate anterior compartment examination. The blade is then repositioned to retract anteriorly for examination of the posterior compartment. Finally, both blades are inserted simultaneously, one anteriorly and one posteriorly, to isolate the vaginal apex and facilitate examination of the cervical or cuff support. The posterior blade is slowly withdrawn to examine the posterior wall. Next, with the posterior blade in place, the patient is asked to strain. Foreshortening of the posterior wall causes expulsion of the blade and suggests a compromise in the level I support (DeLancey, 1992) (cardinal-uterosacral ligament complex) of the vault; if the blade remains in place, this could represent an isolated rectocele or enterocele without vault prolapse. Evaluation for occult SUI should be performed with the anterior wall supported. SUI can be masked if significant prolapse “kinks” the urethra and outlet.

Several classification systems are used to quantify POP, the most widely used of which are the **Baden-Walker classification** (Baden et al, 1968) and the **Pelvic Organ Prolapse-Quantification system**, known as the POP-Q (Bump et al, 1996). The two systems are

A

Point	Description	Range of values
Aa	Anterior vaginal wall 3 cm proximal to the hymen	−3 cm to +3 cm
Ba	Most distal position of remaining upper anterior vaginal wall	−3 cm to +tvL
C	Most distal edge of cervix or vaginal cuff scar	—
D	Posterior fornix (N/A if posthysterectomy)	—
Ap	Posterior vaginal wall 3 cm proximal to the hymen	−3 cm to +3 cm
Bp	Most distal position of remaining upper posterior vaginal wall	−3 cm to +tvL
gh (genital hiatus)	Measured from middle of external urethral meatus to posterior midline hymen	—
pb (perineal body)	Measured from posterior margin of gh to middle of anal opening	—
tvL (total vaginal length)	Depth of vagina when point D or C is reduced to normal position	—

B

Figure 71-2. A, Landmarks for the POP-Q system. B, POP-Q points of reference. (A, From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10–7.)

juxtaposed in Figure 71-1. In the POP-Q system, which was created in an effort to provide objectivity to POP quantification, nine specific points of measurement are obtained in relation to the hymenal ring, as illustrated in Figure 71-2. Six vaginal points labeled Aa, Ba, C, D, Ap, and Bp are measured during Valsalva maneuver. Points above the hymen are considered negative, and points below the hymen are positive. The genital hiatus (gh) represents the size of the vaginal opening, while the perineal body (pb) represents the distance between the vagina and the anus. The total vaginal length (tvL) is measured by reducing the prolapse and measuring the depth of the vagina. Table 71-3 contains the POP-Q staging criteria, a simplified presentation of the POP-Q system, and Figure 71-3 illustrates an example of the application of the system.

A neurologic examination is important in any patient with a known or suspected neurologic condition. Attention to the patient's gait, speech, cognitive status, facial symmetry, sensation in the lower extremities, perineal and perianal regions, lower extremity motor strength, and vaginal and pelvic floor strength can provide helpful

Figure 71-3. Line drawing example of posterior support defect. The anterior compartment is well supported. Bp is the leading point of the prolapse relative to the reference point of the hymen. At +5, Bp is 5 cm beyond the hymen. Point C designates the cuff position. Taking into consideration a total vaginal length (tvL) of 8 cm, the cuff has descended 2 cm. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10–7.)

TABLE 71-3 POP-Q Staging Criteria

STAGE	CRITERIA
0	Aa, Ap, Ba, Bp at −3 cm and C or D ≤ −(tvL − 2) cm
I	Stage 0 criteria not met and leading edge < −1 cm
II	Leading edge ≥ −1 cm but ≤ +1 cm
III	Leading edge > +1 cm but < +(tvL − 2) cm
IV	Leading edge ≥ +(tvL − 2) cm

information. Mobility and cognitive status can play a role in urinary continence insofar as both can affect a patient's ability to reach the facilities in a timely fashion. The **bulbocavernosus reflex (BCR)**, which is representative of sacral nerve root levels 2 to 4 (S2–4), is present in 70% of normal females and 100% of normal males. The BCR is considered positive when squeezing of the glans penis or clitoris results in anal and pelvic floor contraction that can be detected visually or by rectal examination. Alternatively, applying traction to an indwelling Foley catheter to pull the balloon against bladder neck should also precipitate a BCR.

A digital rectal examination (DRE) is important in men to assess the prostate for size, nodularity, or tenderness. In the female, the DRE can facilitate assessment of the rectovaginal septum. Demonstration of a rectocele can be facilitated via anterior pressure applied by a finger placed in the rectum. Anal sphincter tone, which is a reflection of the function at S2–4, is particularly important in neurologic patients with PFD. Patients are asked to voluntarily tighten the pelvic floor as if attempting to stop the flow of urine midstream. Laxity in the rectal sphincter tone may suggest a possible neurologic defect, but it also may be due to patient lack of understanding regarding how to voluntarily control the specific muscle groups necessary for contraction.

In men, genitourinary examination as it pertains to voiding function also should include evaluation of the penis for meatal stenosis and, particularly in the postprostatectomy patient, visible urinary leakage with coughing and straining. Examination for leakage is ideally performed with the patient in the standing position.

KEY POINTS: PHYSICAL EXAMINATION

- A properly performed physical examination is imperative in the evaluation of patients with PFDs.
- The Centers for Medicare and Medicaid Services require specific elements of both male and female genitourinary examination to meet coding guidelines (see [Box 71-2](#)).
- Assessment of POP ideally should be performed in both the supine and standing positions.
- Several classification and quantification systems are available for assessment of POP, the most widely used of which (Baden-Walker and POP-Q) are illustrated in [Figures 71-1 and 71-2](#).
- Neurologic and rectal examinations should be performed in appropriate patients to obtain complete clinical information important in the assessment of lower urinary tract and pelvic floor function.

Supplemental Evaluation

A variety of measures are available to supplement the history and physical examination in patients with PFDs. Instruments exist to quantify symptoms, their effects on QoL, and the degree of bother experienced by patients with PFDs. **Most experts concur that a urinalysis (UA) and PVR measurement should be considered in the majority of patients undergoing evaluation for incontinence.** However, beyond this, there are no universally agreed-upon standards regarding the roles of other studies, such as endoscopy, UDS, radiographic imaging, and various modalities of symptom quantification, including voiding diaries, pad tests, and questionnaires ([Zimmern et al, 2010](#)). In an effort to address this, the AUA and the Society of Urodynamics, Female Pelvic Medicine, and Urogenital Reconstruction (SUFU) published guidelines based on the current literature ([Dmochowski et al, 2010](#); [Gormley et al, 2012](#); [Winters et al, 2012](#)).

According to the guidelines, a UA is part of the minimum requirement for proper evaluation of the patient with an overactive bladder (OAB). Urine culture and PVR can be obtained at the discretion of the clinician. The guidelines state that UDS, cystoscopy, and renal ultrasound should not be a part of the initial evaluation of the patient with uncomplicated OAB ([Gormley et al, 2012](#)). Evaluation of the index patient with SUI should include PVR assessment. UA, UDS, pad tests, cystoscopy, and imaging can be considered ([Dmochowski et al, 2010](#)) in specific situations such as those outlined in [Box 71-3](#). In circumstances in which further investigation is considered, the value and accuracy (sensitivity and specificity) of the information provided by the given assessment method should be considered in relation to the cost and morbidity of the examination.

BOX 71-3 Circumstances That Warrant Consideration of Supplemental Evaluation

Inability to establish a diagnosis based on the patient's symptoms and initial evaluation
 Concomitant overactive bladder symptoms
 Prior lower urinary tract surgery including anti-incontinence surgery
 Known or suspected neurogenic bladder
 Negative stress test
 Abnormal urinalysis (e.g., unexplained hematuria or pyuria)
 Elevated postvoid residual
 High-grade pelvic prolapse (\geq grade 3)
 Evidence of dysfunctional voiding

Symptom Quantification Instruments

Voiding Diaries. Instruments such as voiding diaries, questionnaires, and pad tests have been developed to aid in the quantification of urinary loss, both symptomatically and volumetrically. **Voiding diaries can provide both diagnostic and therapeutic advantages. The use of diaries often helps patients realize their pattern of urination and is more accurate than recall** ([McCormack et al, 1992](#); [Siltberg et al, 1997](#); [Stav et al, 2009](#)). Furthermore, the diary can provide patients with insights into those behaviors that can be altered to decrease urinary frequency ([Burgio, 2004](#)).

Several studies have demonstrated the adjunctive role that diaries can have in the diagnosis and management of incontinence. Diaries can be helpful over routine subjective history because it has been demonstrated that patient recall is not often as accurate as a formal voiding diary in ascertaining urinary frequency. In a retrospective review of 601 patients who underwent sling surgery and completed bladder diaries, only 47% were accurate about their daytime frequency; 51% overestimated their diurnal frequency, and this overestimation was exaggerated in those who reported voiding more than 10 times per day ([Stav et al, 2009](#)). Overestimation rates were similar between patients with and without OAB symptoms. Interestingly, 93% of women in this study were accurate about their nighttime frequency. In another study of women with urinary incontinence, it was noted that the overestimation of incontinence episode frequency occurred more often in those patients who were more bothered by their incontinence. Conversely, Ku and associates ([Ku et al, 2004](#)) found a poor correlation between subjective nocturnal frequency and that noted by 164 patients on their frequency volume charts. [Wyman and colleagues \(1988\)](#) similarly showed a higher correlation of diary-reported frequency in the daytime versus the night.

[Martin and associates \(2006b\)](#) performed a meta-analysis of 121 in 6099 papers that compared two or more diagnostic techniques for incontinence and showed that diaries are most cost-effective when used in conjunction with history, particularly in patients undergoing treatment for detrusor overactivity. It should be noted, however, that diaries should not substitute for more formal studies in selected patients. One study that retrospectively assessed the Larsson frequency/volume chart as compared to the cystometrogram in 216 patients demonstrated the sensitivity and specificity of the chart with regard to detrusor overactivity to be 52% and 70%, respectively, and with regard to SUI, 66% and 65%, respectively ([Tincello and Richmond, 1998](#)). For daily clinical practice, 24-hour diaries should suffice to obtain valuable clinical information regarding LUT function; in academic studies, longer diaries may be requested, but this should be balanced with the well-established knowledge that the more complex a given instrument is (i.e., the more data requested), the lower patient compliance will be in completing it ([Groutz et al, 2000](#)).

Questionnaires and Quality of Life Instruments

Questionnaires can provide a very helpful complement to the patient history and patient-reported outcomes. A plethora of instruments to evaluate symptoms, degree of bother, and QoL in patients with incontinence and PFDs have been developed in an effort to provide optimal assessment of outcomes and eliminate the confounding issue of physician bias; many have been validated. [Table 71-4](#) contains validated questionnaires highly recommended by the International Consultation on Incontinence (ICI). One such instrument, the modular ICIQ, was developed by the ICI in an effort to collaboratively develop a universally applicable instrument that could be used internationally to assess pelvic floor function in both clinical practice and research settings ([Abrams et al, 2005a, 2005b](#)) and has accordingly been translated in 38 languages. The short form of the ICI questionnaire (ICIQ-SF) has been shown to correlate nicely with both the 1-hour ([Franco et al, 2008](#)) and 24-hour ([Karantanis et al, 2004](#)) pad tests for evaluation of the severity of SUI. Another comparison of the 24-hour pad test, the ICIQ-SF, the International Prostate Symptom Score (IPSS), and the Post-operative

TABLE 71-4 Instruments Highly Recommended by the Fourth International Consultation on Incontinence for Urinary Incontinence, Overactive Bladder, Lower Urinary Tract Symptoms, and Pelvic Organ Prolapse Patient Reported Outcomes

QUESTIONNAIRE	POPULATION	PURPOSE OF INSTRUMENT
HEALTH-RELATED QUALITY OF LIFE (HRQOL)		
BFLUTS (Bristol Female Lower Urinary Tract Symptoms Questionnaire) (also named ICIQ-FLUTS) (Jackson et al, 1996)	Women, incontinence	To assess female LUTS, particularly incontinence, measure impact on QoL and evaluate treatment outcome
DAN-PSS-1 (Danish Prostatic Symptom Score) (Hansen et al, 1995)	Men, BPH	To evaluate males with LUTS suggestive of uncomplicated BPH
ICIQ-UI-SF (ICIQ Urinary Incontinence Short Form) (Avery et al, 2004)	Men and women, urinary symptoms	To assess symptoms and impact of urinary incontinence in clinical practice and research
ICSmale (ICIQ-MLUTS) (Donovan et al, 1996)	Men with LUTS and possible BPH	To provide evaluation of occurrence and bother of LUTS and their impact on the lives of men with BPH
ICS-QoL (Donovan et al, 1997)	Men with LUTs and possible BPH	To assess impact of LUTS on the lives of men with LUTS
IIQ (Incontinence Impact Questionnaire) (Wyman et al, 1987)	Women, UI, SUI	To assess impact of incontinence on HRQOL, primarily in patients with SUI
IIQ-7 (IIQ-short form) (Uebersax et al, 1995)	Women, UI, SUI	To assess impact of urinary incontinence on HRQOL
I-QOL (ICIQ-Uiqol) (urinary incontinence-specific QoL instrument) (Wagner et al, 1996)	Women, UI	To assess QoL of women with urinary incontinence
KHQ (King's Health Questionnaire) (ICIQ-LUTSqol) (Kelleher et al, 1997)	Men and women, OAB	To assess the impact of LUTS on HRQOL
N-QoL (ICIQ-Nqol; Nocturia QoL) (Abraham et al, 2004)	Men and women	To assess the impact of nocturia on QoL
OABq-SF (Coyne et al, 2002)	Men and women, OAB	Shortened version of OAB-q to evaluate both continence and incontinence symptoms of OAB and their impact on QoL
OAB-q (ICIQ-OABqol) (Coyne et al, 2002)	Men and women with OAB wet and OAB dry	To evaluate both OAB-wet and OAB-dry symptoms and their impact on HRQOL
PRAFAB (Protection, Amount, Frequency, Adjustment, Body image) (Hendriks et al, 2007)	Women, UI	To evaluate treatment effects for UI in women
UISS (Urinary Incontinence Severity Score) (Stach-Lempinen et al, 2001)	Women, UI	To assess symptom severity and impact of urinary incontinence on everyday life
Urolife (BPH-QoL9) (Lukacs et al, 1997)	Men, BPH	To assess the impact of BPH and its treatment on the QoL of patients
SCREENERS		
B-SAQ (Bladder-Self-Assessment Questionnaire) (Basra et al, 2007)	Women	Screening tool for the presence of bothersome LUTS in women
LUSQ (Leicester Urinary Symptom Questionnaire) (Shaw et al, 2002)	Men and women, LUTS	Condition-specific screener of storage LUTS (urgency, frequency, nocturia, and incontinence)
OAB-SS (OAB Symptom Score) (Blaivas et al, 2007)	Men and women, LUTS with and without OAB	7-item tool to measure overall symptom severity resulting from the four index symptoms of OAB
OAB-V8 (OAB Awareness Tool) (Coyne et al, 2005)	Men and women, OAB	8-item screening tool for use in primary care setting to identify patients who may have OAB
QUID (Questionnaire for Urinary Incontinence Diagnosis) (Bradley et al, 2005)	Women, UI and SUI	6-item tool to diagnose SUI and UI
SYMPTOM BOTHER		
PPBC (Patient Perception of Bladder Condition) (Coyne et al, 2006)	Men and women	To assess patients' subjective impression of their current urinary problems Developed as a global assessment of bladder condition
UDI-6 (Urogenital Distress Inventory-6/short form) (Uebersax et al, 1995)	Women	To assess LUTS bother, including incontinence, in women

TABLE 71-4 Instruments Highly Recommended by the Fourth International Consultation on Incontinence for Urinary Incontinence, Overactive Bladder, Lower Urinary Tract Symptoms, and Pelvic Organ Prolapse Patient Reported Outcomes—cont'd

QUESTIONNAIRE	POPULATION	PURPOSE OF INSTRUMENT
URGENCY		
IUSS (Indevus Urgency Severity) (Nixon et al, 2005)	OAB with urgency incontinence, men and women	To quantify the level of urgency associated with each toilet void as measured during standard voiding diaries
POP SYMPTOMS AND QOL		
PFDI (Pelvic Floor Distress Inventory) (Barber et al, 2001)	Women	To quantify the symptoms caused by pelvic prolapse
PFIQ (Pelvic Floor Impact Questionnaire) (Barber et al, 2001)	Women	To quantify the effects of pelvic prolapse on quality of life

BPH, benign prostatic hyperplasia; HRQOL, health-related QOL; ICIQ, International Consultation on Incontinence Questionnaire; ICS, International Continence Society; MLUTS/FLUTS, male/female lower urinary tract symptoms; OAB, overactive bladder; QoL, quality of life; SF, short form; SUI, stress urinary incontinence; UI, urgency incontinence.

Data from Staskin DR. In: Patient-Reported Outcome Assessment. Fourth International Consultation on Incontinence, report of Committee 5, part 5B. 2009. p. 363–412.

Patient Global Impression of Improvement (PGI-I) score in 26 men after perineal sling placement confirmed the construct validity of these instruments (Twiss et al, 2007a). There was a strong correlation demonstrated between the ICIQ-SF and PGI-I scores and the percentage reduction in 24-hour pad weight. At the time of this writing, available validated ICI symptom modules include the ICIQ-MLUTS (male LUTS) long and short forms, ICIQ-FLUTS (female LUTS) long and short forms, ICIQ-UI short form, ICIQ-N (nocturia), ICIQ-OAB, and ICIQ-VS (vaginal symptoms). Validated QOL modules applying to LUTS (ICIQ-LUTSqol), urinary incontinence (ICIQ-UIqol), OAB (ICIQ-OABqol), and nocturia (ICIQ-Nqol), as well as modules that assess male and female sexual function related to urinary symptoms (ICIQ-MLUTSsex and ICIQ-FLUTSsex), are also available for use. Additional modules covering bowel function, pediatric LUTS, and neurogenic LUTS, as well as modules assessing QoL symptoms pertaining to the same, and additional sexual function and treatment satisfaction modules are under development (Abrams et al, 2010; Bristol Urological Institute, 2014).

A study examining the incontinence- and non-incontinence-related pelvic floor symptoms evaluated by two widely used symptom tools, the UDI-6 and the ICIQ-UI, demonstrated that both symptom questionnaires were sound and correlated with each other and independently with the QoL scores, as measured by the ICIQ-7 and I-QOL (van de Vaart et al, 2010). This study also uncovered the interesting finding that the delay in time to consultation with a physician was associated with greater bother, emphasizing the importance of heightened awareness of PFDs in the female patient population.

In the meta-analysis by Martin and colleagues (2006b), two studies showed a high sensitivity (.82 to .92) of question 3 in the Urogenital Distress Inventory for SUI; the specificity was .51 to .69. In this study, history alone had a pooled sensitivity of .92 (95% confidence interval [CI]) and a specificity of .56 for the diagnosis of SUI and a sensitivity of .61 and specificity of .87 for the diagnosis of detrusor overactivity. It should be borne in mind, however, that for higher risk interventions, such as surgery, the most accurate testing available remains multichannel UDS studies.

Pad Tests

Pad tests are generally used for academic purposes. The ICS recommends both a 3-day bladder diary and pad weight test as proper measures for symptom quantification in incontinence research (Lose et al, 2001). However, although pad tests can be helpful in quantifying leakage, they are tedious and cumbersome for the

patients. Moreover, they do not provide information that is necessary for daily routine clinical practice. The Fourth ICI Committee on initial assessment did not recommend pad tests as part of the initial evaluation in the incontinent patient (Staskin, 2009). From an academic standpoint, however, many investigators advocate for pad tests in clinical trials, because pad tests can provide objective, precise information for assessment of actual volume of urine lost over an established period.

According to the Third ICI, greater than 1.3 g of urine loss is considered a positive 24-hour pad test (Tubaro, 2005), whereas others consider up to 8 g of urine loss in 24 hours to be normal (Lose et al, 1989). This variability poses a potential limitation on the utility of the pad test; many investigators use the pad test for research purposes. Vaginal secretions should be taken into consideration, although the volume attributable to normal vaginal secretions may be as low as 0.3 g in 24 hours (Karantanis et al, 2003). O'Sullivan and colleagues (2004) evaluated 110 women with incontinence with two 1-hour pad tests and 7 consecutive days of 24-hour pad tests. The severity of the leakage was analyzed in relation to UDS parameters, age, parity, and pelvic floor muscle strength, showing increased severity with increasing age and parity and in those women who demonstrated detrusor overactivity. The authors proposed that 24-hour loss of 1.3 to 20 g, 21 to 74 g, and greater than 75 g to signify "mild," "moderate," and "severe" incontinence, respectively. Another study of 144 randomly selected Danish women who underwent 24-hour pad testing revealed a similar loss of urine in the self-reported continent and incontinent groups or 3.1 and 3.3 g, respectively (Ryhammer et al, 1998).

It is generally agreed that the 24-hour pad test is a clinically more useful tool than the 1-hour pad test (Lose et al, 1989; Matharu et al, 2004); in fact, the test-retest reliability and the predictive value of the 1-hour test in the diagnosis of female incontinence have been shown to be poor (Lose et al, 1986, 1988; Simons et al, 2001; Constantini et al, 2008). Others have advocated the opposite extreme, suggesting that a 20-minute pad test with a standardized bladder volume of 250 mL instilled into the bladder via catheterization had superior sensitivity compared to the 1-hour test conducted via the ICS standardized method of pad testing (Wu et al, 2006). The ICS method, described in 1988, requires the patient to drink 500 mL of sodium-free liquid in 15 minutes followed by a 30-minute resting period before proceeding with the recommended physical activity (Abrams et al, 1988). One potential concern about this method is the lack of standardization of bladder volume.

Parenthetically, pad use per day obtained in the patient history is a measure frequently used to quantify urine loss, but one study

demonstrated that this is an unreliable measure of incontinence (Dylewski et al, 2007). A retrospective chart review of 145 males and 116 females who underwent artificial urinary sphincter placement and sling surgery, respectively, and who had completed a self-reported pad-use query was performed and the patients were asked to bring three pads into their clinic visit: one dry “reference” pad and the incontinence pads used for the 24-hour periods preceding and including the day of their visit. The pads were quantified and weighed to determine the grams of urine per pad. All patients also underwent a 24-hour pad weight test. Only a very weak correlation was found between reported pad usage and the 24-hour pad weight, with pad usage measuring only 38% of the variability of incontinence volume. Additionally, whereas the pads per day decreased, the grams of urine per pad increased with increasing age.

Dye Testing

Dye testing can be helpful to verify that the leakage represents urine versus another fluid such as vaginal discharge or peritoneal fluid and to substantiate the diagnosis of urinary tract fistulae. **Oral phenazopyridine** 100 to 200 mg three times per day colors the urine orange, and this simple test can confirm that the leaking fluid is indeed urine. Diagnosis of a vesicovaginal or urethrovaginal fistula can be supported by blue or orange staining of an intravaginal tampon after **intravesical instillation of methylene blue or pyridium dissolved in sterile water or saline**. In the case of a suspected *ureterovaginal* fistula, **intravesical methylene blue with concurrent oral pyridium** can elucidate the fistula location based on the staining pattern on the vaginal tampon. Orange staining suggests a ureteral communication, whereas blue staining connotes a bladder communication (Raghavaiah, 1974). The clinician must keep in mind that simultaneous vesicovaginal and ureterovaginal fistulae can occur.

KEY POINTS: SUPPLEMENTAL EVALUATION

- It has been demonstrated that patient subjective history alone often does not reflect an accurate or complete picture of their symptomatology complex.
- Several instruments designed to facilitate symptom quantification have been developed and include tools such as voiding diaries, symptom and QoL questionnaires, and pad tests.
- Voiding diaries can be both diagnostic and therapeutic, because they can provide patients with insights into behaviors that may be contributing to their voiding symptoms.
- Pad tests may be helpful, particularly in the academic setting, to quantify incontinence symptoms. Loss of up to 8 g of urine in 24 hours may be considered normal, although the ICI considers loss of greater than 1.3 g to be a positive 24-hour test.
- Validated questionnaires are available to assess symptoms and QoL in patients with PFDs.

Urinalysis

It is generally agreed that UA plays a fundamental role in the evaluation of the incontinent patient or the patient with LUTS (Abrams et al, 2009a). The UA provides information such as the presence of hematuria, pyuria, glucosuria, or proteinuria that can be indicative of conditions that can cause *secondary* incontinence. As indicated by the screening dipstick analysis, a microanalysis and/or culture should be performed that may provide guidance regarding further testing or therapy for conditions related to or independent of urinary incontinence.

Postvoid Residual

The volume of urine left in the bladder after routine voiding is termed the *postvoid residual (PVR)*, and some authors have sug-

gested that PVR should be evaluated in all incontinent patients (Tubaro, 2005; Gormley, 2007). This simple test, which can be performed via in-and-out catheterization or using noninvasive transabdominal ultrasonography, evaluates the bladder's emptying ability and can be helpful in the diagnosis of overflow incontinence. The 2012 AUA/SUFU SUI guidelines state that clinicians considering invasive therapy in patients with SUI should assess PVR to evaluate bladder emptying, because patients with elevated PVRs preoperatively are at increased risk for developing voiding difficulties postoperatively (Winters et al, 2012). It is important to establish baseline bladder emptying, particularly in patients with stress incontinence who may be considered for an anti-incontinence procedure or patients with urinary urgency who may be candidates for therapies aimed at decreasing bladder contractility.

A number of studies have demonstrated that ultrasonography is comparable to catheterization in evaluating the PVR, although there are no officially established volumes that define normal or impaired emptying. The Agency for Healthcare Research and Quality (AHRQ) suggests that PVR less than 50 mL represents adequate emptying and PVR greater than 200 mL represents inadequate emptying (U.S. Department of Health and Human Services, 1992). There is no consensus recommendation regarding the significance of PVR between 50 and 200 mL. In one study, Gehrich and associates (2007) enrolled 96 healthy women who presented for routine well-woman checkup. Exclusion criteria included urinary incontinence more than twice per week, urinary retention, neurologic disease, or symptomatic POP. The mean and median PVRs were 19 mL (0 to 145 mL) and 24 ± 29 mL. Fifteen percent had a PVR greater than 50 mL, and 95% had PVR less than 100 mL. Another study compared PVR measurements obtained by three-dimensional (3D) bladder scan versus catheterization in 170 women who were undergoing evaluation for SUI but who had never undergone previous pelvic surgery (Tseng et al, 2008); 35.5% had PVR greater than 50 mL, and 15.9% had PVR greater than 100 mL. Ultrasonography offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR above 100 mL. Although several studies support the accuracy of the bladder scan (Al-Shaikh et al, 2009), some suggest that certain sonographic devices may provide more accurate information than others (Chani et al, 2008).

Cystoscopy

Endoscopic examination of the bladder is important as a means to evaluate for intravesical or intraurethral pathology that may be contributing to the patient's symptomatology. Bladder tumors, bladder stones, cystitis, and intravesical or intraurethral foreign bodies such as mesh or suture can contribute to irritative voiding symptoms, recurrent urinary tract infections (UTIs), and incontinence. Patients with a history of previous pelvic floor reconstructive surgery should be evaluated for eroded materials into the LUT. The ureteric orifices should be identified and evaluated for morphology, position, number, and efflux. The bladder mucosa is examined for trabeculation (which can be suggestive of bladder outlet obstruction [BOO] and/or detrusor overactivity) and estrogen status, and the urethra is assessed for foreign bodies, stricture, diverticulum or fistula, and position.

The role of preoperative cystourethroscopy has been addressed by few authors. Anger and associates (2007) analyzed Medicare claims data to assess the effects of preoperative cystoscopy and UDS studies on sling outcomes. The data of a random 5% sample of Medicare beneficiaries during an established 18-month period were used to assess the likelihood of undergoing postoperative studies in those who did and did not undergo the same studies preoperatively. Although patients who underwent preoperative cystoscopy were less likely to undergo postoperative cystoscopy (23.4% vs. 35.2%, $P < .0001$) or UDS (19.3% vs. 34.0%, $P < .0001$), there were no significant differences in complications or repeat incontinence procedures between the groups. However, Cundiff and Bent (1996) reported that cystoscopy changed the diagnosis and management in 6 of 84 women (7%) who underwent both cystoscopy and UDS for evaluation of LUT dysfunction. Findings included transitional

cell carcinoma, cystitis glandularis, intravesical suture, and a urethral diverticulum.

Although the use of routine cystoscopy is not advocated in the evaluation of the “index” SUI patient, it should be considered in patients who present with urinary urgency, hematuria, or other irritative symptoms, particularly if they have undergone a previous anti-incontinence procedure, pelvic radiation, or pelvic prolapse repair.

Urodynamics

Similar to cystourethroscopy, the routine use of UDS is the subject of much discussion; however, one should or may consider UDS in patients who are considering invasive, potentially morbid or irreversible surgery; have failed previous pelvic floor reconstruction; or have mixed incontinence, urinary urgency, or obstructive symptoms; and in patients who have elevated PVRs or neurologic disease. UDS is also useful to confirm or refute a diagnosis and can facilitate patient selection and counseling. The benefit of UDS in these situations is to establish baseline bladder capacity, compliance, sensation, stability, and sphincter function before further surgical or therapeutic manipulation. A comprehensive review of UDS is presented in Chapter 73.

LUT function can be simply categorized into storage and emptying. Each of these categories is affected by the bladder (detrusor) and the outlet. Two main questions should be considered in the evaluation of the incontinent patient. (1) Is the problem at hand a storage issue, an emptying issue, or a combination of the two? (2) Is the cause of the identified problem a detrusor issue, an outlet issue, or a combination of both?

“Eyeball UDS” is a simple, economically favorable alternative to full multichannel UDS that can be helpful in selected patients. The study can determine bladder sensation, compliance, stability, and capacity, as well as outlet competence and PVR (Blaivas, 1996). After voiding, the patient is placed in the lithotomy position, a Foley catheter is placed, and the PVR is measured. A 60-mL catheter-tip syringe with the barrel removed is placed into the end of the catheter. With the syringe held upright, the bladder is filled with sterile fluid through the syringe. The height of the meniscus above the bladder represents the intravesical pressure. The volumes at first sensation and first desire, normal desire, strong desire to void are recorded. During the filling phase, the meniscus in the syringe is observed for a rise and fall that may represent bladder overactivity or a consistent gradual rise that suggests compromised detrusor compliance. The absence of the abdominal pressure (Pabd) channel limits the ability to accurately determine any abdominal contribution to a change in the water volume in the syringe. The catheter is removed, and a cough stress test is performed by observing the urethra for incontinence during coughing and straining.

Multichannel UDS offers an extensive evaluation of LUT function. The degree of accuracy provided by multichannel UDS is important in a variety of circumstances, including when conservative treatment methods fail; when the diagnosis is unclear; when previous diagnostic procedures are inconclusive; in patients with clinical pictures complicated by radiation therapy, neurologic disease, or prior failed pelvic floor reconstruction or anti-incontinence surgery; or when patients describe symptoms that cannot be confirmed by the clinician. A complete UDS study evaluates the filling/storage phase by filling cystometrogram and the voiding/emptying phase by uroflowmetry.

Catheters are placed into the bladder and the rectum. The bladder catheter measures the actual pressure within the bladder, termed the vesical pressure (Pves). The rectal catheter measures the abdominal pressure (Pabd). The detrusor pressure (Pdet) is a calculated value ($P_{ves} - P_{abd}$) that represents the pressure created by the detrusor independent of the influences of intra-abdominal pressure. During the filling phase, the Pdet is expected to remain low and stable to allow for low-pressure bladder filling. Poorly compliant bladders will show a gradual steady rise in the Pdet as the bladder volume increases. Detrusor overactivity is manifest by

intermittent and unpredictable rises in the Pdet. During the voiding phase, the Pdet may rise as the urine flows. Many women void normally with virtually no rise in Pdet. High Pdet with low flow during voiding suggests BOO. Inability to produce a flow with no Pdet, particularly when accompanied by abdominal straining (represented by an undulant Pabd), may indicate an atonic or hypotonic detrusor.

When making the diagnosis of urodynamic SUI, urethral function should be assessed (Winters et al, 2012). Quantitative measurements such as the Valsalva leak point pressure or maximal urethral closure pressure can be used to guide treatment decisions in patients suspected of having SUI who do not demonstrate leakage with stress maneuvers; stress testing should be repeated with the urethral catheter removed. In patients with high-grade POP without symptoms of SUI, stress testing should be performed with the POP reduced to evaluate for occult SUI.

Electromyography (EMG) and fluoroscopic imaging (video-urodynamics [VURDS]) are helpful adjuncts to the UDS study in selected patients and are covered in detail in Chapter 73. EMG activity is reflective of the activity of the striated muscles of the urethral and anal sphincters and the perineal musculature and can be measured using either surface electrodes or needle electrodes. Although the latter provides more accurate readings, the discomfort caused to the patient and the expertise required for the technique render it far less popular than surface electrodes. The coordination of the EMG and detrusor activity is most helpful during the voiding phase, when failure to relax the pelvic floor can be indicative of pathologic processes. Similarly, recruitment of activity should be noted with BCR and increased abdominal pressure, such as occurs during coughing. VURDS can be useful in the demonstration of anatomy in the upright position and because the bladder and outlet are visualized in real time, VURDS can confirm incontinence in patients in whom the diagnosis is difficult and can provide an accurate measure of leak point pressure. It is also helpful to assess the bladder outlet in patients in whom dysfunctional voiding, primary bladder neck obstruction, or detrusor-sphincter dyssynergia are suspected. Patients also can be evaluated for vesicoureteral reflux (VUR) and bladder or urethral diverticula. Assessment of detrusor pressures in the face of reflux or a large bladder diverticulum can provide important information that would be missed without video imaging.

Recent attention has been placed on scientifically establishing the role and clinical value of UDS. The worth of a test is not solely in its diagnostic accuracy but is also in the improvement of the outcomes of subsequent interventions. UDS is frequently used in the evaluation of patients with PFDs and can be helpful in counseling. Suboptimal outcomes of anti-incontinence procedures are generally attributed to intrinsic sphincter deficiency, detrusor overactivity, or baseline dysfunctional voiding. The deliberation regarding the merit of these theories and the ability of UDS to accurately establish these conditions continues. In a study of 655 women with positive stress tests, 10% did not demonstrate urodynamic-SUI (UDS-SUI) (Nager et al, 2007). A meta-analysis based on a Medline search of the literature between 1975 and 1998 suggested that UDS has a positive predictive value (PPV) of only 56% and 79% for pure SUI and SUI with other abnormalities, respectively, and a positive cough test has PPVs for the same of 55% and 91%, respectively (Harvey and Versi, 2001). The Urinary Incontinence Treatment Network (UITN) reported that UDS did not predict postoperative voiding dysfunction or the risk for need of postoperative surgical intervention (Lemack et al, 2008). In another retrospective study in women who underwent retropubic midurethral sling placement for treatment of mixed incontinence, the median opening detrusor pressure was higher in women with postoperative detrusor overactivity than in those with normal postoperative UDS (Panayi et al, 2009).

Much of the literature to date has been limited by the retrospective design and small cohorts of the available studies. The UITN found that the success of anti-incontinence surgery in patients who demonstrated UDS-SUI was nearly twice that of those with non-UDS-SUI, although this trend did not reach statistical significance

(Nager et al, 2008). The same group showed that treatment outcomes at 1 year for women with uncomplicated demonstrable stress incontinence were not inferior in patients who did not undergo preoperative UDS compared to those who did (Nager et al, 2009, 2012). Although a study by Anger and associates (2007) did not definitively establish an effect of preoperative UDS specifically on sling outcomes, there was a clear demonstration of a two-fold (significant) increased likelihood of undergoing postoperative UDS studies in those patients who did not undergo the study preoperatively compared to those who did.

With the implementation of health care reform in 2014, cost-effectiveness is at the forefront of discussion. Based on decision-analytic (hypothetical) models, one group deemed UDS not cost-effective relative to the basic office evaluation (Weber and Walters, 2000; Weber et al, 2002). However, one must remain mindful that UDS provides information, not only about the overall diagnosis, but also regarding important subtle findings that may direct the clinician in treatment planning and counseling (Summitt et al, 1992; Patel and Chapple, 2008). Although it has been suggested that UDS may not be necessary or useful in patients with straightforward non-neurologic conditions who would be considered for initial conservative management (Colli et al, 2003; National Institute for Health and Clinical Excellence, 2006; Winters et al, 2012), others have shown that as many as 20% of patients with presumed pure SUI may have UDS findings that might alter their treatment or outcomes (Digesu et al, 2009).

Reproducibility of UDS studies and interpretation of the examination has been questioned by several studies (Van de Beek et al, 1997; Gupta et al, 2004; Zimmern et al, 2006; Gacci et al, 2007). Others have demonstrated that intraobserver interpretation (interpretation repeated by the same individual) is superior to interobserver interpretation (same study read by two different individuals) for both pressure-flow analyses (Digesu et al, 2003) and filling/voiding studies (Whiteside et al, 2006). Still others have demonstrated no difference in interobserver and intraobserver interpretation, but that live interpretation of a study provides different readings than post-hoc interpretation, suggesting that intangible experiential factors may play a role in the interpretation of UDS studies (Smith et al, 2009).

Approximately 40% of patients with POP describe SUI symptoms (Grody, 1998), and UDS-SUI is demonstrated in 70% to 75% of patients with prolapse (Roovers and Oelke, 2007). Occult SUI unmasked by reduction of prolapse is reported to be present in 36% to 80% (Richardson et al, 1983; Bergman et al, 1988; Chaikin et al, 2000), and 11% to 50% of clinically continent patients will develop de novo SUI after repair of high-grade prolapse (Bergman et al, 1988; Borstad and Rud, 1989; Gallentine and Cespedes, 2001). Women who demonstrated preoperative UDS-SUI before sacrocolpopexy were more likely to develop postoperative SUI irrespective of whether they received a concomitant Burch colposuspension (Visco et al, 2008). Conversely, after a retrospective review of the records of 76 patients who underwent POP repair, Roovers and colleagues (2007) reported that no UDS parameters predicted postoperative incontinence. In an effort to determine the need for prophylactic sling placement in patients undergoing surgery for high-grade POP, Ballert and coworkers (2009) followed a UDS protocol designed to address the urethra in a standardized fashion. They concluded that in patients who did not subjectively describe or urodynamically demonstrate SUI preoperatively, the risk of intervention because of BOO after sling placement was equivalent to the risk of intervention for SUI in patients who did not receive a sling. The Colpopexy and Urinary Reduction Efforts (CARE) trial was designed to evaluate whether a Burch colposuspension performed at the time of sacrocolpopexy for prolapse in stress-continent women reduced postoperative SUI. The large prospective randomized study was stopped after the first interim analysis at 3 months when 23.8% of the women in the Burch group and 44.1% of the control group met criteria for SUI ($P < .001$) (Brubaker et al, 2006). The cohort was continued at 2 (Brubaker et al, 2008) and 7 (Nygaard et al, 2013) years postoperatively, demonstrating a continued advantage of prophylactic Burch for SUI

at both time points, though the failure rates of sacrocolpopexy increased in both groups by the 7-year follow-up.

In select patients, particularly those with OAB symptoms and/or known neurogenic bladder, UDS can be helpful in determining the risk for progression to upper tract deterioration. Detrusor overactivity, poor compliance, detrusor-external sphincter dyssynergia, high detrusor storage pressures, VUR, and BOO represent potential risk factors for the development of upper tract disease, particularly in patients with sustained Pdet greater than 40 cm H₂O (McGuire et al, 1981; Blaivas and Barbalias, 1984; Choniem et al, 1989, 1990).

Although multichannel UDS remains the most accurate tool with which to evaluate LUT function, it is clear that multi-institutional randomized prospective studies are of dire importance in addressing many of the unanswered questions regarding the role and contribution of UDS to patient care, counseling, and optimization of treatment modalities. Further evaluation of the accuracy of the study and most importantly, the impact of UDS on patients, treatments, and treatment outcomes must be pursued. The UDS guidelines provide parameters around the use of UDS based on an exhaustive review of the current literature.

KEY POINTS: URODYNAMICS

- UDS is the most accurate tool available for the assessment of LUT function and provides information regarding urine storage and emptying as they are affected by the bladder and the bladder outlet.
- Although the use of routine UDS for straightforward incontinence is a topic of discussion, UDS should be strongly considered before intervention in patients who have a complex clinical picture because of failed previous treatment or surgery, mixed incontinence, obstructive symptoms, significantly elevated PVR, neurologic disease, or other medical conditions that may contribute to the LUT function, such as diabetes mellitus, pelvic prolapse, or history of radiation therapy.
- "Eyeball UDS" may provide an approximate picture of the bladder capacity, sensation, stability, compliance, and outlet resistance when formal UDS is not available.
- Multichannel UDS offers extensive evaluation of LUT function. It involves direct measurement of bladder and intra-abdominal pressure (Pves and Pabd, respectively) and a calculated assessment of detrusor pressure that is independent of abdominal pressure (Pdet). $Pves - Pabd = Pdet$.
- Fluoroscopic imaging provides useful adjunctive information, such as the position and status of the bladder base and bladder neck, the presence of VUR, and direct visualization of urinary leakage under real-time circumstances. Video imaging should be considered when the diagnosis cannot be made with certainty without simultaneous understanding of the anatomy in conjunction with the functional findings.

Radiographic Imaging

Voiding Cystourethrogram. Standard imaging studies are not necessary in the initial evaluation of women with uncomplicated incontinence (Artibani et al, 2002; Artibani and Cerruto, 2005). However, upper and lower urinary tract imaging in patients in whom renal damage or pelvic pathologic conditions are suspected should be performed. Voiding cystourethrogram (VCUG) is optional in patients with recurrent UTIs, but can be helpful in the diagnosis of a urethral diverticulum or VUR. VCUG can provide valuable information regarding the contour of the bladder, the presence of VUR, the position of the bladder base with and without straining with the patient in an upright posture, and the position

and configuration of the bladder neck during voiding. Fluoroscopic imaging also can provide visualization of subtle leakage with coughing or Valsalva maneuver that may be difficult to detect with direct examination.

Ultrasonography. Upper tract imaging is recommended in patients with chronic urinary retention, suspected extraurethral incontinence, untreated severe POP, and neurogenic detrusor dysfunction considered to be at high risk for renal damage. Patients with high-grade POP can develop upper tract obstruction and hydronephrosis related to ureteral kinking resulting from the prolapse. Ultrasonography provides a noninvasive sensitive and specific method of assessing the upper tracts for hydronephrosis. Ultrasonic imaging of the bladder neck for urinary leakage and descent during stress also has been used to diagnose SUI with documented pooled sensitivity and specificity rates in the range of .84 to .89 and .82 to .89, respectively (Martin et al, 2006b).

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) has been proposed as an ideal method by which to evaluate the anatomy of the bladder neck and urethra with good correlation with functional studies (Macura, 2006; Macura et al, 2006; Macura and Genadry, 2008). MRI has also been advocated for evaluation of pelvic floor relaxation and POP (Boyadzhyan et al, 2008), particularly in patients undergoing evaluation for complex multicompartmental pelvic floor reconstruction (Macura, 2006; Boyadzhyan et al, 2008) and has been shown to identify changes related to the uterosacral ligaments before and after surgical repair of prolapse (Martin et al, 2006a). MRI also may be helpful in identifying patients in whom a urethral diverticulum may be present. Although urethral diverticula can cause symptoms of urinary leakage, pelvic pain, obstructive voiding symptoms, recurrent UTIs, dyspareunia, and a multitude of nonspecific symptoms, up to 20% of diverticula may be completely asymptomatic (Rovner, 2007). In patients with reports of SUI who are found to have a urethral diverticulum, a simultaneous anti-incontinence surgery may be considered, in which case proper radiographic imaging, such as can be obtained with MRI, can provide anatomic information germane to optimal surgical planning.

High-resolution MRI allows detailed visualization of the urethra, the external sphincter, and the supporting structures. MRI evaluation focusing specifically on the muscle volume of the sphincter, defects in the sphincteric musculature, funneling of the bladder neck, symmetry of the pubococcygeus muscle or urethral supporting ligaments, increase in the size of the retropubic space or urethrovesical angle, and abnormal vaginal shape may be helpful in the diagnosis of SUI resulting from intrinsic sphincter deficiency or urethral hypermobility (Macura, 2006). To facilitate assessment of POP using MRI, the HMO (H-line, M-line, organ prolapse) system was developed (Pannu et al, 2000).

Evaluation is performed using rapid half-Fourier T2-weighted images in the midsagittal plane during maximal patient straining. There are three fixed points in the HMO system: A, the inferior margin of the pubic symphysis; B, the posterior levator plate; and C, the junction between the first and second coccygeal segments. Two fixed reference points include point B and the pubococcygeal line (PCL), drawn between points A and C. Line H, drawn between A and B, represents the anterior-posterior hiatal dimension. Line M, which is the shortest distance between point B and the PCL, represents the degree of pelvic descent. The O component comprises the shortest distance between the H line and the most caudal aspect of the evaluated organ during Valsalva maneuver. Prolapse is graded based on the organ location relative to the H-line in centimeters.

Dynamic MRI can provide integral information in the preoperative assessment of POP, particularly in patients in whom the pelvic examination is difficult and inconclusive. The sensitivity, specificity, and PPV of MRI for cystoceles has been reported to be 70% to 100%, 83% to 100%, and 97% to 100%, respectively; 42% to 100%, 54% to 81%, and 33% to 60%, respectively, for vaginal vault prolapse; 87% to 100%, 80% to 83%, and 75% to 91%, respectively, for enteroceles; 83%, 100%, and 100%, respectively, for uterine prolapse, and 87%, 72%, and 66%, respectively, for

rectoceles (Gousse et al, 2000; Deval et al, 2003). Other authors have found that dynamic MRI does not correlate well with clinical findings in patients with middle compartment (i.e., apical) prolapse, and much of the literature suggests that the study should be used only as an adjunct to clarify anatomy in complex cases (Cortes et al, 2004) or under investigational circumstances (Tubaro, 2005). Similarly, many authors agree that the posterior compartment is not as easily visualized on dynamic MRI. A study using intrarectal air during MRI did not demonstrate any value of dynamic MRI for evaluation for rectoceles over videoproctography, the latter of which was more sensitive in identifying rectoceles (Matsuoka et al, 2001). For optimal visualization of rectoceles, intrarectal gel is used to provide hyperintensity on T2-weighted images (Macura, 2006; Boyadzhyan et al, 2008; Law and Fielding, 2008).

MANAGEMENT

Incontinence Treatment Overview

The approach to treatment of incontinence is contingent on a clear understanding of the cause and pathophysiology underlying the patient's symptoms. The clinician must first determine whether the cause of the symptomatology complex is a bladder or an outlet problem, or, not uncommonly, a combination of both. Therapeutic options should be considered with the goal of providing an individualized patient-directed treatment plan based on the patient goals and risk-benefit and cost-benefit ratios. **Proper representative counseling is paramount to properly align patient expectations and goals and what is possible to achieve.** Adjunctive studies such as UDS may be performed (and in select situations *should* be performed) to provide complete information on which clinical decisions can be made as outlined in the SUI, OAB, and UDS guidelines (Dmochowski et al, 2010; Gormley et al, 2012; Winters et al, 2012).

Management of incontinence can be categorized into nonsurgical and surgical options. Underlying causes such as UTI, BOO, bladder stones, foreign body, or bladder tumor should be identified and addressed first. Box 70-3 in Chapter 70 provides an overview of the treatment options available for the management of incontinence; a detailed review of the various therapeutic options is presented in Chapters 79 through 87.

Treatment of incontinence must be tailored to the patient's needs, goals, and expectations and requires proper counseling on the part of the clinician. Some patients may be satisfied with protective garments and/or urine collection devices, such as indwelling or condom catheters, or barriers, such as urethral plugs or external occlusion devices. Intervention for patients with urgency incontinence may range from behavioral and dietary modification to biofeedback or pharmacotherapy. **Per the OAB guidelines, behavioral therapy (e.g., fluid management, dietary modification, and bladder training) is considered to be the first line of therapy (Gormley et al, 2012).** Medications can be added subsequently, but are technically considered to be second-line therapy. Sacral neuromodulation, onabotulinumtoxinA detrusor injection, and enteric augmentation of the bladder may be considered in patients with refractory symptoms.

Similarly, patients with SUI may benefit variably from conservative measures using pelvic floor muscle exercises, biofeedback, electrical stimulation, and pharmacotherapy. Urethral bulking injection therapy can provide an intermediate option between nonsurgical and surgical therapies, but surgery remains the mainstay of treatment for SUI. Although needle suspensions remain only as a point of historic discussion, retropubic suspensions have persisted as a reasonable treatment option for SUI. However, slings, using a variety of materials, insertion approaches, and anchoring techniques, have effectively become the standard options for women with SUI. In 2011 the U.S. Food and Drug Administration (FDA) released a safety communication regarding mesh placed transvaginally specifically for the repair of pelvic prolapse (U.S. Food and Drug Administration, 2011a, 2011b, 2013). Unfortunately, subsequent media communication regarding mesh litigation created

patient confusion and concern, prompting a joint response from SUFU and the American Urogynecologic Society (AUGS) in 2014 (AUGS and SUFU, 2014).

Injection therapy has not proved a particularly viable option for the treatment of male SUI (which occurs most commonly after prostatectomy for treatment of adenocarcinoma of the prostate), and follow-up of the outcomes with male slings is still early. In a review of the literature, Cerruto and colleagues (2013) reported on a pooled cure rate from 160 studies, none of which were controlled; 77.4% were “cured” at a median follow-up of 15 months. The artificial urinary sphincter remains the prevailing treatment option for post-prostatectomy incontinence. The artificial urinary sphincter has been used rarely for treatment of SUI in women. In the fortunately rare cases of complete urethral devastation, bladder neck closure or urinary diversion can be considered.

Pelvic Prolapse Treatment Overview

New techniques have been explored to improve on the traditional pelvic floor reconstructive approaches that depend on the inherently compromised tissues of the patient with POP. The use of synthetic and biologic graft materials to improve the integrity and durability of POP repairs has become popularized over the past decade, though graft use remains a point of robust discussion and debate. Novel anatomic approaches and kits have been developed and have resulted in a dramatic increase in the number of clinicians participating in pelvic floor reconstruction, but controversy surrounding the safety of synthetic mesh grafts has quickly changed the landscape again.

The goal of POP repair is to restore the normal anatomy and function of the vagina and the lower urinary and gastrointestinal tracts. The decision regarding whether to proceed with a transvaginal or a transabdominal approach depends on which of the three compartments is affected, the degree of prolapse, and patient and surgeon preference. Apical prolapse involving the uterus typically results in a hysterectomy, although uterine sparing techniques can be performed. Post-hysterectomy apical prolapse can be addressed transvaginally with a uterosacral ligament suspension or a sacrospinous ligament fixation. Several contemporary devices that aim to facilitate high prolapse reduction have been introduced, but follow-up is early. Nevertheless, the sacrocolpopexy, a transabdominal approach that can be performed either open or minimally invasively using laparoscopy or robotic assistance, remains the gold standard repair for apical prolapse. A Y-shaped mesh typically composed of polypropylene is attached to the apex of the vagina and bridged to the sacrum to return the vagina to its normal axis.

New techniques of pelvic floor reconstruction continue to emerge parallel with increasing efforts to understand pelvic floor anatomy and function. A comprehensive overview of current surgical management of pelvic prolapse is presented in Chapter 83.

CONCLUSION

The ultimate goal of pelvic floor reconstruction is to restore the normal anatomy and function of the vagina, bladder, and surrounding structures. Proper evaluation of the pelvic floor anatomy and function should theoretically maximize the probability of favorable outcomes. Additionally, with a growing emphasis on QoL enrichment and a simultaneously increasing cost of health care, along with the implementation of the Patient Protection and Affordable

Care Act, economically sound and durable treatments are the aspiration. Accordingly, efforts to develop methods by which to evaluate and quantify symptoms and assess outcomes continue. New techniques designed to provide safe and successful options to achieve maximal symptom relief and QoL improvement continue to evolve, and tissue engineering is an exciting new frontier. As our comprehension of the pelvic floor advances, further approaches to treat PFDs will undoubtedly arise.

Types of Urinary Incontinence

Evaluation

Urinary incontinence (UI) is defined by the International Continence Society as the **involuntary loss of urine** (Abrams et al, 2002) or, in other words, any leakage of urine. It is part of storage lower urinary tract symptoms (LUTS) and can result from a variety of causes. It is therefore important to understand the etiology of the UI and to evaluate and assess appropriately the men who are suffering with UI to manage them accordingly, as this condition can be a social and hygienic problem that affects quality of life (QoL).

UI should be **described by specifying relevant factors** such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and QoL, the measures used to contain the leakage, and whether or not the individual seeks or desires help because of UI. The condition must be distinguished from sweating or urethral discharge.

UI in men is prevalent but less so than in women. Prevalence in men varies from 1% to 39% depending on the definition used, variation in populations, response options, and participation rates (Tikkinen et al, 2013). In a population survey in Canada, 5.4% of male respondents presented with UI (26% had stress urinary incontinence [SUI], 15% had mixed urinary incontinence [MUI], and 58% had urgency urinary incontinence [UUI]) (Bettez et al, 2012). In the EpiLUTS study (Coyne et al, 2012), the prevalence of UI in men was 46%. However, this included various forms of urinary symptoms, such as postmicturition incontinence, nocturnal enuresis, and urinary leakage with no definable cause. A total of 5.6% of men reported UUI only, 0.8% SUI only, 1.4% MUI, 6.3% UUI and another form of UI, and 1.2% SUI and another form of UI.

TYPES OF URINARY INCONTINENCE

There are different types of UI (Abrams et al, 2002) and it is important to know the differences among them, as these differences would affect management.

Stress Urinary Incontinence

SUI is the complaint of involuntary loss of urine on effort or physical exertion (e.g., sporting activities), or on sneezing or coughing (Abrams et al, 2002). In other words, SUI is effort-related or activity-related incontinence, and this appellation might be preferred in some languages to avoid confusion with psychological stress. SUI occurs when the intra-abdominal pressure exceeds the intraurethral pressure. SUI is more common in women than in men and usually

Treatment

Conclusion

occurs in men only after a prostatectomy in which the external urethral sphincter is damaged.

Urgency Urinary Incontinence

UUI is the complaint of involuntary loss of urine associated with urgency. It was formerly known as urge urinary incontinence (Abrams et al, 2002). However, because it must be preceded by urgency, the terminology has changed to urgency urinary incontinence (Abrams et al, 2009; Tooze-Hobson et al, 2012). It is part of the **overactive bladder (OAB) syndrome**, and 90% of men who experience UUI will have detrusor overactivity (DO) on urodynamics (Hashim and Abrams, 2006). Patients who suffer with UUI have *wet OAB*.

Mixed Urinary Incontinence

MUI is the complaint of involuntary loss of urine associated with urgency and also associated with effort, physical exertion, sneezing, or coughing. Thus those with MUI experience both UUI and SUI (Abrams et al, 2002). This condition is uncommon in men although it may occur after prostatectomy.

Nocturnal Enuresis

Nocturnal enuresis is the complaint of **involuntary urinary loss of urine that occurs during sleep** (van Kerrebroeck et al, 2002). In other words, it is wetting the bed at night while asleep and not being aware of it. Nocturnal enuresis is differentiated from nocturia, which is intentionally getting out of bed to pass urine at night and is preceded and followed by sleep.

Nocturnal enuresis has an estimated prevalence of nearly 10% in children aged 7 years. However, in 2% to 3% of children it may persist into adulthood (Vande Walle et al, 2012). Nocturnal enuresis may also manifest later in life and it is an important symptom, especially in men, as it may indicate that these men are in high-pressure chronic urinary retention, which is usually associated with upper tract dilation and the risk of renal failure.

Continuous Urinary Incontinence

Continuous urinary incontinence describes the complaint of **continuous involuntary loss of urine** (Tooze-Hobson et al, 2012). This is a rare symptom and only exists when there is a fistula, for example a prostate-rectal fistula. Sometimes men describe severe incontinence as continuous, when the underlying etiology may be related to SUI, UUI, or MUI.

Postmicturition Leakage or Dribble

This condition evokes complaints of involuntary leakage of urine following the completion of micturition and occurring after the man has dressed himself, usually after he has left the toilet (Abrams et al, 2002).

Insensible Urinary Incontinence

Insensible urinary incontinence is a complaint of UI when the patient is unaware of how it occurs but becomes aware that he is wet (Tooze-Hobson et al, 2012).

Other Types of Urinary Incontinence

These types may be situational; for example, the report of incontinence during sexual intercourse in women is termed coital incontinence. Giggle incontinence occurs when girls are giggling. Both of these types are rare in male patients.

KEY POINTS: TYPES OF URINARY INCONTINENCE IN MEN

- SUI
- UUI
- MUI
- Nocturnal enuresis
- Postmicturition dribble
- Continuous UI
- Insensible UI

EVALUATION

History

Men presenting with symptoms of UI must be evaluated with a **thorough history and directed physical examination**. It is important to enquire about:

- When do they leak? For example, when they cough, when they have urgency, at night while asleep, or other times.
- How often do they leak? For example, every night, daily, or another frequency.
- Are there any precipitating factors that make leakage worse? For example, cold weather, putting the key in the door (latch-key incontinence), or other factors.
- Was there any previous surgery to the prostate or bladder or was there major abdominal surgery that could have led to damage to the sacral plexus?
- How much do they leak? For example, wet the underwear, flood the outer clothing or floor, or other amounts.
- Does the patient wear pads? If so, what type of pads, how many pads, what size of pads, or what other containment products are used, such as condom catheter or perhaps a change of underwear in the event of a leak?
- Has the patient tried any medications, and what medications does he take?
- Are there any neurologic problems and/or back pain that might suggest a neurologic cause for UI?
- How is the patient's sexual, erectile, and bowel function?

A general medical, surgical, and social history must be obtained, including drug allergies, smoking habits, and quantifying any alcohol or caffeine intake.

Physical Examination

An examination, with the patient in a lying position, should include:

- The abdomen to feel for any masses and especially for a distended bladder and hernias.

- The external genitalia to examine the foreskin and external urethral meatus, as some men may be suffering with *overflow incontinence* resulting from a stenosis of the external urethral meatus or a severe phimosis.
- The prostate via a digital rectal examination to feel the size and consistency of the prostate, as well as asking the patient to perform a pelvic squeeze to assess the strength of the pelvic floor.
- The anal canal and lower rectum to feel for anal tone and sensation and to assess rectal emptying.
- Lower-limb neurologic examination to check reflexes, muscle strength, and sensation.
- Cough test: After the previous examinations are completed, ask the patient to cough to see if there is any leakage, and then ask the patient to stand and to cough again to check for SUI.

First-Line Investigations

After the clinical examination is completed, bedside investigations must be performed.

Measurement of Height and Weight to Calculate Body Mass Index

The **body mass index (BMI)** is a good measure of obesity, and, in men who suffer with SUI, providing advice about weight loss may be helpful. However, there is little evidence that weight loss in men is useful; the evidence is extrapolated from women suffering with SUI. Also, related to men with SUI who have an artificial urinary sphincter (AUS), the less pressure there is intra-abdominally, and therefore the less pressure transmitted to the bladder, the less likely that these men would leak through the inflated artificial sphincter. This is because the AUS is a mechanical device, usually inserted with a pressure-regulating balloon of 61 to 70 cm H₂O, and if the intra-abdominal pressure exceeds that, then the patient will leak.

Urinalysis

Urinalysis is usually performed using a dipstick with multiple parameters including leukocytes and nitrites (to check for infection), glucose (to check for diabetes), blood (to check for hematuria), specific gravity (to ensure adequate fluid intake), pH (to see if the urine is basic or acidic), and ketones.

If there is any abnormality on the dipstick urinalysis, then the specimen is sent for microscopy, culture, and sensitivity. Appropriate investigations are also then initiated such as a flexible cystoscopy and ultrasound scan of the renal tract if there is hematuria.

Bladder Diary

The **bladder diary** (Fig. 72-1) is a vital investigational tool, as it provides objective information on the number of episodes the patient is leaking and the number of pads being used, how many times the patient is passing urine during the day and night, the average and maximum voided volumes and hence bladder capacity, the type and amount of fluid being drunk, assessment for nocturnal polyuria, and whether or not there is any urgency.

Several different bladder diaries are available. However, none of these diaries has been fully validated except for the International Consultation on Incontinence Questionnaire Bladder Diary (ICIQ-BD) (Bright et al, 2012).

The number of days a bladder diary must be completed has also been the subject of several publications, and the most recent recommendation is that a 3-day bladder diary would offer the same information as a 7-day one without being too exhaustive for patients (Dmochowski et al, 2005). It is important, however, to tell patients to try to complete the diary so that they include a combination of weekdays and weekends, and the entries should be representative

ICIQ-BLADDER DIARY

Please complete this 3-day bladder diary. Enter the following in each column against the time. You can change the specified times if you need to. In the time column, please write BED when you went to bed and WOKE when you woke up.

Drinks Write the amount you had to drink and the type of drink.

Urine output Enter the amount of urine you passed in milliliters (mL) in the urine output column, day and night. Any measuring jug will do. If you passed urine but couldn't measure it, put a tick in this column. If you leaked urine at any time, write LEAK here.

Bladder sensation Write a description of how your bladder felt when you went to the toilet using these codes:

0 - If you had no sensation of needing to pass urine, but passed urine for "social reasons"; for example, just before going out, or unsure where the next toilet is.

1 - If you had a normal desire to pass urine and no urgency.

"Urgency" is different from normal bladder feelings and is the sudden compelling desire to pass urine that is difficult to defer, or a sudden feeling that you need to pass urine, and, if you don't, you will have an accident.

2 - If you had urgency but it had passed away before you went to the toilet.

3 - If you had urgency but managed to get to the toilet, still with urgency, but did not leak urine.

4 - If you had urgency and could not get to the toilet in time, so you leaked urine.

Pads If you change a pad, put a tick in the pads column.

Here is an example of how to complete the diary:

Time	Drinks		Urine output (mL)	Bladder sensation	Pads

Bladder sensation codes

0 - No sensation of needing to pass urine, but passed urine for "social reasons"

1 - Normal desire to pass urine and no urgency

2 - Urgency but it had passed away before you went to the toilet

3 - Urgency but managed to get to the toilet, still with urgency, but did not leak urine

4 - Urgency and could not get to the toilet in time, so you leaked urine

Figure 72-1. International Consultation on Incontinence Questionnaire Bladder Diary (ICIQ-BD).

of patients' day-to-day lifestyles. The ICIQ-BD validation has shown that 3 days is the appropriate length to include the day-to-day changes in frequency and so forth.

Quality-of-Life Questionnaires and Patient-Reported Outcome Measures

Patients are unlikely to suffer significant morbidity from most types of UI, but UI does cause significant impact on QoL. It is therefore prudent to assess the impact of UI on a patient's QoL with a validated questionnaire.

The International Prostate Symptom Score (IPSS or AUA-SI) is the most commonly used questionnaire for men. However, this questionnaire is useless for men with UI, simply because the IPSS does not measure incontinence.

The ICIQ-UI short form (ICIQ-UI-SF; Fig. 72-2) is a simple, short questionnaire that helps differentiate between SUI and UUI (Avery et al, 2004). The alternative is the longer form ICIQ-male LUTS questionnaire (ICIQ-MLUTS; Fig. 72-3 on the Expert Consult website), which includes the advantages of asking about the storage and voiding symptoms covered by the IPPS and asking about the bother of each (Abrams et al, 2006).

Both the bladder diary and QoL questionnaire not only help in the assessment of patients but also help in looking at treatment effects if repeated after the patient has been treated.

Pad Testing

There is much controversy about the use of **pad testing** and the duration of time for which it should be performed. Should it be done for 1 hour or 24 hours? How many days should it be

performed? Do pretreatment pad loss volumes predict outcomes? All these are questions that have not yet been answered by high-quality research. Also, pad testing does not help to differentiate between the different types of incontinence, especially UUI and SUI.

Most guidelines have not recommended the use of pad testing. However, pad testing can be useful in attempting to quantify the amount of leakage a patient experiences and perhaps in planning treatment accordingly. There is also disagreement in the literature as to what the definition of mild, moderate, and severe incontinence is, and whether or not the number of pads should be used to classify UI severity, or whether urine loss measured by pad weights should be used. Some would suggest that the use of one pad is considered mild, two to four pads is moderate, and more than four pads is severe, but patients sometimes change pads because of hygienic reasons rather than for necessity (Tsui et al, 2013). Increased pad weight is therefore probably a better measure of the severity of UI, and usually less than 200 g/day is considered mild, 200 to 400 g/day is moderate, and more than 400 g/day is severe (Kumar et al, 2009). However, it should be emphasised that these cut points have not been properly validated.

Urine Flow Rate and Postvoid Residual

Urine flow rates help in showing the pattern of the flow and the speed at which the patient is voiding, and ultrasound after voiding measures the postvoid residual (PVR). These measurements are inexpensive and easy to perform, and they are noninvasive. It is important, however, to learn how to interpret the measurements. A fast-rising flow rate may indicate an OAB, and a slow-rising one with a long tail on the flow curve may indicate obstruction. If there is a high PVR, the obstruction might cause

Urinary symptoms

Many people experience urinary symptoms some of the time. We are trying to find out how many people experience urinary symptoms, and how much they bother them. We would be grateful if you could answer the following questions, thinking about how you have been, on average, over the PAST FOUR WEEKS.

1. Please write in your date of birth:

DAY MONTH YEAR

2a. During the day, how many times do you urinate, on average?

one to six times	<input type="checkbox"/>	0
seven to eight times	<input type="checkbox"/>	1
nine to ten times	<input type="checkbox"/>	2
eleven to twelve times	<input type="checkbox"/>	3
thirteen times or more	<input type="checkbox"/>	4

2b. How much does this bother you?
Please ring a number between 0 (not at all) and 10 (a great deal)

0	1	2	3	4	5	6	7	8	9	10
not at all										a great deal

3a. During the night, how many times do you have to get up to urinate, on average?

none	<input type="checkbox"/>	0
one	<input type="checkbox"/>	1
two	<input type="checkbox"/>	2
three	<input type="checkbox"/>	3
four or more	<input type="checkbox"/>	4

3b. How much does this bother you?
Please ring a number between 0 (not at all) and 10 (a great deal)

0	1	2	3	4	5	6	7	8	9	10
not at all										a great deal

4a. Do you have a sudden need to rush to the toilet to urinate?

never	<input type="checkbox"/>	0
occasionally	<input type="checkbox"/>	1
sometimes	<input type="checkbox"/>	2
most of the time	<input type="checkbox"/>	3
all of the time	<input type="checkbox"/>	4

4b. How much does this bother you?
Please ring a number between 0 (not at all) and 10 (a great deal)

0	1	2	3	4	5	6	7	8	9	10
not at all										a great deal

Initial number

ICIQ-UI SF

CONFIDENTIAL

DAY MONTH YEAR

Today's date

Many people leak urine some of the time. We are trying to find out how many people leak urine, and how much this bothers them. We would be grateful if you could answer the following questions, thinking about how you have been, on average, over the PAST FOUR WEEKS.

1 Please write in your date of birth:

DAY MONTH YEAR

2 Are you (tick one):

Female ☐ Male ☐

3 How often do you leak urine? (Tick one box)

never ☐ 0
 about once a week or less often ☐ 1
 two or three times a week ☐ 2
 about once a day ☐ 3
 several times a day ☐ 4
 all the time ☐ 5

4 We would like to know how much urine you think leaks.
How much urine do you usually leak (whether you wear protection or not)?
 (Tick one box)

none ☐ 0
 a small amount ☐ 2
 a moderate amount ☐ 4
 a large amount ☐ 6

5 Overall, how much does leaking urine interfere with your everyday life?
 Please ring a number between 0 (not at all) and 10 (a great deal)

0 1 2 3 4 5 6 7 8 9 10
 not at all a great deal

ICIQ score: sum scores 3+4+5

6 When does urine leak? (Please tick all that apply to you)

never – urine does not leak ☐
 leaks before you can get to the toilet ☐
 leaks when you cough or sneeze ☐
 leaks when you are asleep ☐
 leaks when you are physically active/exercising ☐
 leaks when you have finished urinating and are dressed ☐
 leaks for no obvious reason ☐
 leaks all the time ☐

Thank you very much for answering these questions.

Figure 72-2. International Consultation on Incontinence Questionnaire Urinary Incontinence Short Form (ICIQ-UI-SF).

chronic retention and if this is associated with high bladder-filling pressures then nighttime UI during sleep may occur.

It is recommended that at least two flows be performed to ensure that they are representative of the manner in which the patient normally voids (Reynard et al, 1996; Garcia-Mora et al, 2013).

Measurement of Prostate-Specific Antigen

There is much controversy about prostate-specific antigen (PSA) testing, which will not be discussed here. However, if the testing is not going to change management, and if the digital rectal examination was normal, it should not be performed unless the patient requests it and is fully counseled about PSA testing.

Blood Tests

Blood tests should be tailored according to the patient history and examination. If a patient is diabetic then renal function tests and glucose are indicated. In general, if it is an index case of UI or SUI with no PVR, then blood tests are not indicated; however the clinician may opt to perform blood tests because they are helpful in assessing renal function and it would be difficult to select those patients with renal insufficiency (Madersbacher et al, 2004).

Endoscopy and Imaging

Cystoscopy and imaging with radiograph or urinary tract ultrasound are not indicated in patients with UI unless there is

concern that the patient may be suffering with a urethral stricture or another pathology seen on urinalysis, such as blood, or flow tests such as a high PVR.

Urodynamic Studies

Urodynamic studies (UDS), or urodynamics, include studies of the physics and physiology of the lower urinary tract (LUT). Technically this includes flow rates. In everyday practice, however, the term *UDS* means filling cystometry and voiding pressure/flow studies.

The general underlying principle when performing urodynamics is that it should not be performed unless it is going to change the management of the patient and unless it would provide the clinician with more information that would alter his or her management of the patient. Hence, following baseline investigations, most major international guidelines including the International Consultation on Incontinence, the European Association of Urology, and the American Urological Association recommend that patients be treated with conservative therapy and medical therapy before performing urodynamics, and if these treatments fail to control the patient's symptoms and the patient would like to have, or needs, a surgical intervention, then that is when urodynamics is performed—that is, before invasive therapy (Winters et al, 2012).

Urodynamics should be considered in the following situations:

- to identify factors contributing to LUT dysfunction and to assess their relevance
- to predict the consequences of LUT dysfunction on the upper tracts
- to predict the consequences and outcomes of therapeutic intervention
- to confirm and/or understand the effects of interventional techniques
- to investigate the reasons for treatment failure

Filling cystometry aims to define how the bladder and urethra behave during the storage phase. In other words, in an index non-neurologic patient, the bladder can either be normal, or there is DO, or there is poor compliance. If the patient leaks during filling cystometry when a DO wave exists, that then is termed *detrusor overactivity incontinence* (DOI). It is important to mark on the urodynamics trace whether urgency was experienced at that time and whether there were any provocative maneuvers.

The urethra, that is, the external urethral sphincter, can either be competent or incompetent during filling cystometry. If it is competent then the patient will be continent and will not experience SUI. The patient is usually asked to perform Valsalva maneuvers or repeated coughs in the upright position when 200 mL of fluid have been instilled into the bladder. If the patient leaks, then the urethra is incompetent and the pressure at which leakage starts, the abdominal (Valsalva or cough) leak-point pressure, is recorded. Valsalva and coughs are also repeated at the end of the test at maximum capacity if the patient did not leak at 200 mL of bladder filling. If the patient leaks on increasing intra-abdominal pressure, then he is said to have urodynamic stress incontinence (USI) as opposed to SUI; USI is a symptomatic clinical diagnosis before urodynamics is performed.

One important scenario that can occur during urodynamics is cough-induced DOI, which happens when the patient coughs, and this action initiates an involuntary detrusor contraction (DO), and the patient leaks because of the DO contraction rather than because of the raised intra-abdominal pressure generated by the cough. Clinically it sounds as if the patient is leaking because of SUI, whereas the urodynamics shows that he has cough-induced DOI.

If during UDS it is difficult to be certain whether the man has USI or cough-induced DOI then it might be helpful to fill the bladder with the man in a lying position, as then DO is less likely to occur. Then ask him to cough to determine whether he leaks in the absence of DO, which would confirm the diagnosis of USI. If he does not leak with coughing, that is then good evidence that he only has DOI. If he leaks while lying down without DO, then the

patient also has USI and therefore has both DOI and USI, that is, mixed urodynamically proven UI.

After urodynamics is performed and the diagnosis is confirmed, invasive surgical treatment can be offered.

KEY POINTS: INITIAL EVALUATION OF PATIENTS WITH URINARY INCONTINENCE

ESSENTIAL

- History and examination
- Measurement of height and weight to calculate BMI
- Dipstick urinalysis
- Bladder diary, for example ICIQ-BD
- QoL questionnaire, for example ICIQ-UI-SF
- Urine flow rate and measurement of PVR

OPTIONAL

- PSA
- Blood tests, for example urea and electrolytes
- Renal tract imaging
- UDS

TREATMENT

Treatment (Fig. 72-4) of patients suffering with UI can be divided into:

- Conservative
- Medical
- Minimally invasive
- Major surgery

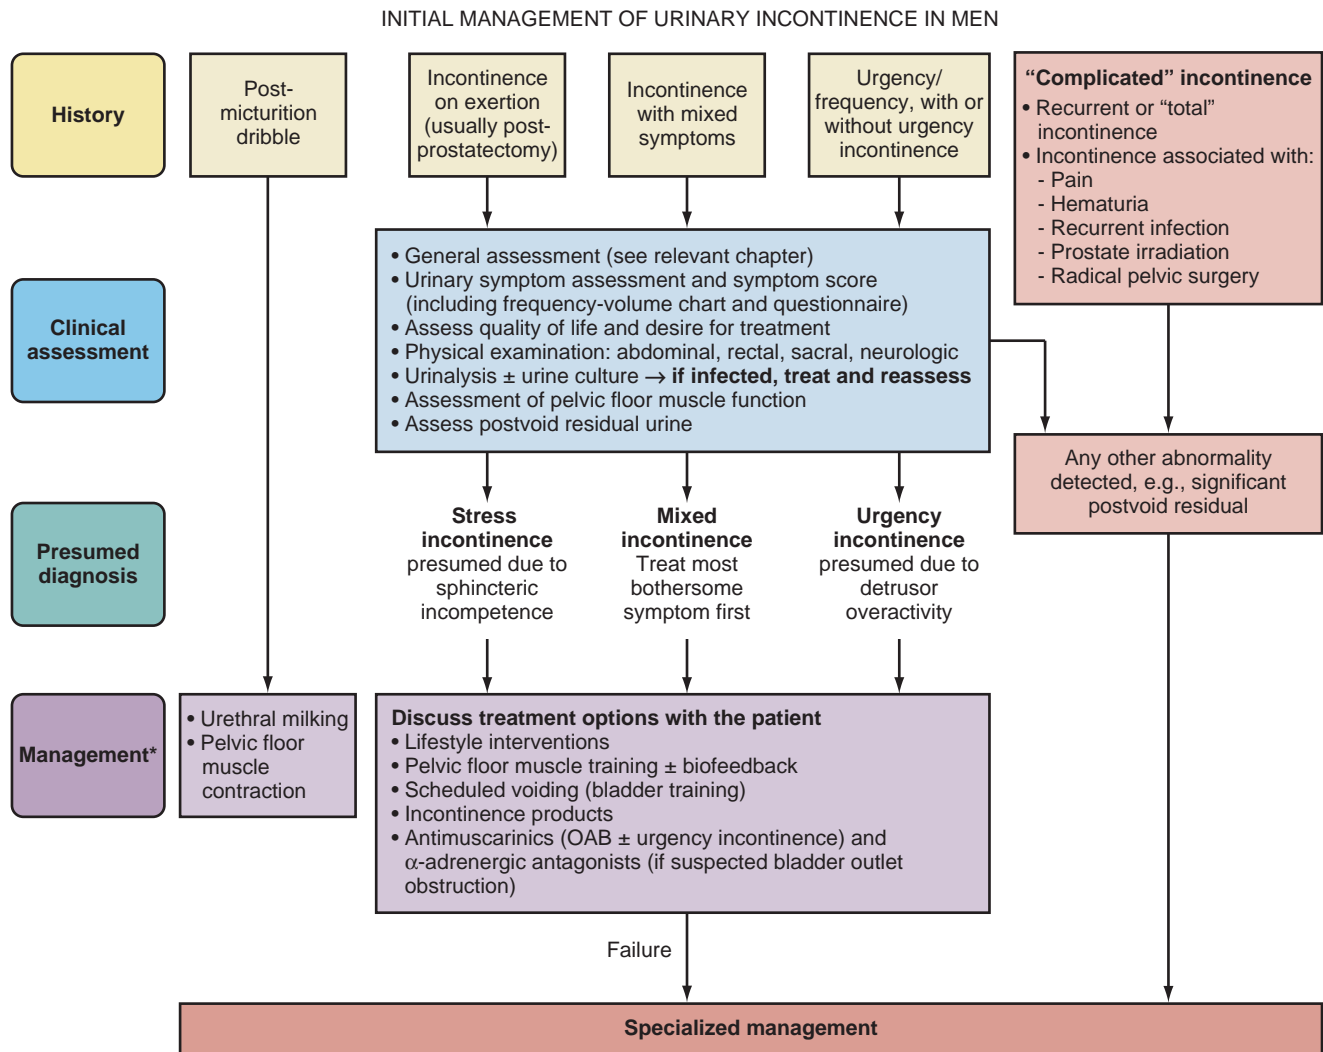

Treatment of Urgency Urinary Incontinence

Initial conservative treatment of UII includes behavioral modifications and lifestyle changes such as reducing fluid input by 25% as long as the patient is drinking more than 1 L/day (Hashim and Abrams, 2008), stopping smoking, reducing weight, and avoiding caffeinated and fizzy drinks that may irritate the bladder. The patient is also taught bladder training and pelvic floor muscle training to supplement the bladder training. These treatments need to be attempted for at least 6 weeks to obtain benefit, and they should ideally be tried for 3 months.

If the previously outlined treatment fails, the patient can then be offered antimuscarinic therapy if there are no contraindications. At least two antimuscarinics must be tried for at least 4 weeks each, starting at a low dose and building up to a maximum dose. There are seven antimuscarinics on the market in the United Kingdom (oxybutynin, tolterodine, fesoterodine, solifenacin, darifenacin, Propiverine, and trospium chloride). Most are oral tablets but oxybutynin is also available in a topical gel formulation (in the United States) and as a skin patch. Each has advantages and disadvantages, and the choice of one in favor of the other depends on several factors, including licensing in the respective country, local guidelines, and clinician and patient preferences. All of the antimuscarinics have Level 1 evidence and Grade A recommendations for their use.

If patients are unable to tolerate antimuscarinics or the antimuscarinics have failed to control symptoms, then patients can be prescribed mirabegron, which is a β_3 agonist that has been licensed for the treatment of OAB in some countries including the United States, the United Kingdom and other European countries, and Japan.

Trials are currently being conducted on combination therapy of an antimuscarinic with a β_3 agonist. In theory, as they work on different receptors they can be used in combination. A phase II trial has shown that the combination therapy of mirabegron and solifenacin is superior to monotherapy with a safe side-effect profile

A

*At any stage of the patient's care pathway, management may need to include continence products.

Figure 72-4. International Consultation on Incontinence algorithm on initial (A) and specialized (B) management of urinary incontinence in men. (From Abrams P, Andersson KE, Artibani W, et al. 5th international consultation on incontinence, recommendations of the International Scientific Committee: evaluation and treatment of urinary incontinence, pelvic organ prolapse and faecal incontinence. In: Abrams P, Cardozo L, Khoury S, et al, editors. *Incontinence. Paris: International Consultation on Urological Diseases and European Association of Urology; 2013. p. 1895-911.*)

(Abrams et al, 2013). More often than not, both conservative and medical therapies are initiated at the same time to provide patients with a quicker and better relief of symptoms.

If conservative and medical therapies fail to control symptoms and the patient requests further treatment, invasive urodynamics is then performed to confirm DO and/or DOI, and minimally invasive surgery, where indicated and available, is offered. This can either be in the form of cystoscopic intradetrusor injections of botulinum toxin-A, percutaneous sacral nerve stimulation (SNS), or percutaneous tibial nerve stimulation (PTNS).

Botox is the only licensed formulation of botulinum toxin A, for idiopathic UII at 100 units, and for neurogenic DO at 200 units. Patients using Botox should be warned of the risk of urinary retention and they should be able and willing to perform intermittent catheterization. In addition, the injections must be repeated on average every 9 months.

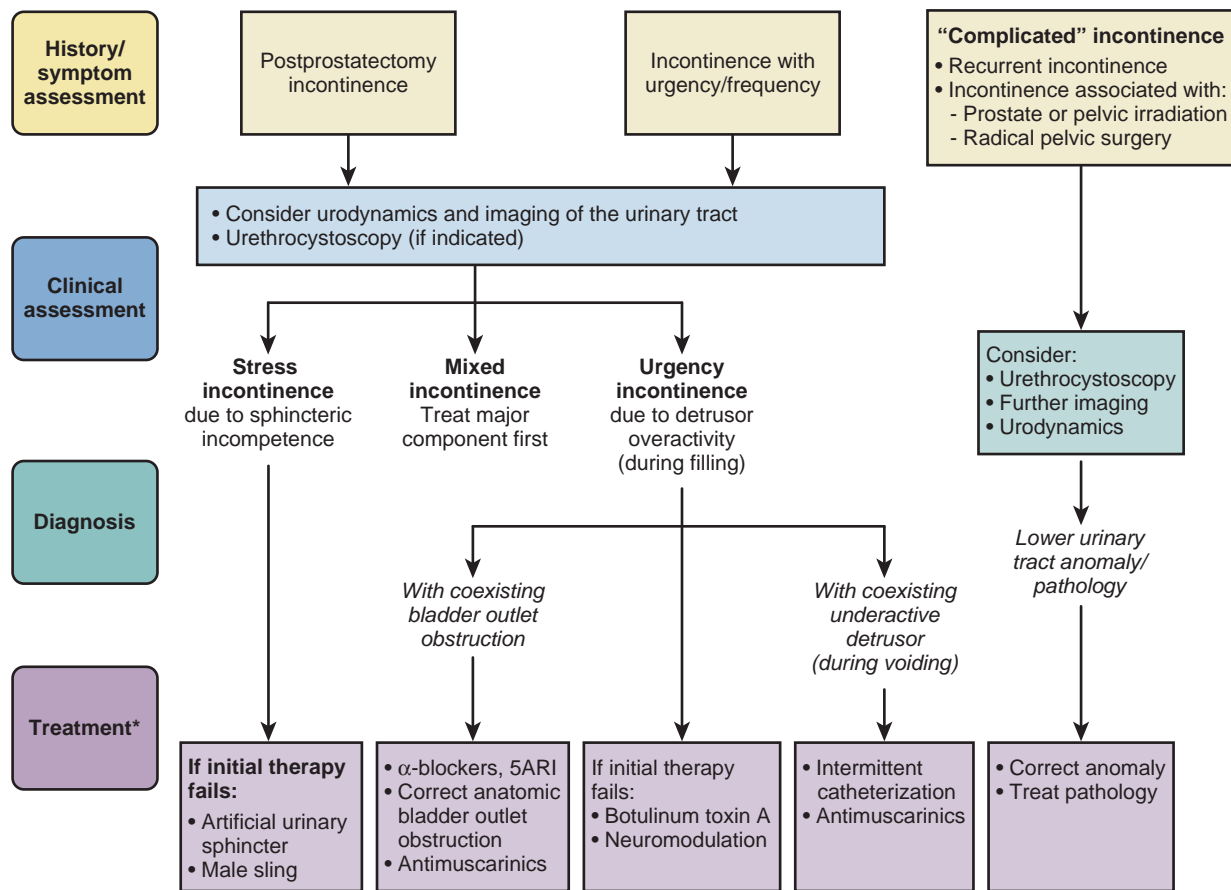

SNS involves a test phase with a wire and external stimulator for 1 week, and a second stage with a tined lead and battery if the first one is successful, which is usually defined as more than a 50% improvement in symptoms. The mechanism of action of SNS is not

clear; however, it is believed that it modulates the nerves supplying the bladder. The battery is changed every 7 years, on average, depending on the amount of use. The cure rate of UII is 39% and an improvement of greater than 50% is seen in 67% of patients. Long-term success has been evaluated with more than 10 years' follow-up with sustained results (Bettez et al, 2012).

PTNS, on the other hand, although licensed for OAB in some countries, does not seem to offer the same degree of benefit as Botox or SNS and as such PTNS is not widely used. The response rate is 54% to 81% (Bettez et al, 2012). PTNS involves inserting a needle into the ankle on the tibial nerve, similar to acupuncture. It is administered as 30-minute sessions once per week for 12 weeks and then it is maintained after that once per month. Patients find it laborious especially if it means traveling for long distances to receive treatment. In theory, this treatment can be self-administered if the patients are taught how to do it. The cost is higher than antimuscarinics therapy and there are no long-term outcome data available.

If these minimally invasive treatments fail and the patient continues to be bothered by symptoms, then the only treatments

SPECIALIZED MANAGEMENT OF URINARY INCONTINENCE IN MEN

B

*At any stage of the patient's care pathway, management may need to include continence products.

Figure 72-4, cont'd

remaining are major surgical operations, unless the patient prefers to use containment products such as pads or a permanent suprapubic catheter. **Surgical options include augmentation cystoplasty, in its various forms, or an ileal conduit with or without a sub-total cystectomy.** In adults, autoaugmentation is no longer recommended for the treatment of DO, because the long-term success of this procedure is not high.

Treatment of Stress Urinary Incontinence

SUI is treated initially with pelvic floor muscle training for at least 3 months. Ideally the training should be supervised to allow the best chance of success (Hay-Smith et al, 2012). If this treatment fails to control symptoms then surgical options should be considered.

The most common cause for SUI in men occurs following prostatectomy. **After radical prostatectomy, it is recommended that no surgical treatment be considered until at least 6 to 12 months subsequently, as some patients will continue to improve (Herschorn et al, 2010).** While they are waiting to improve, patients can use a penile clamp such as *Dribble-Stop*, or, more frequently, containment products are used such as a condom catheter, urethral or suprapubic catheter, or incontinence pads.

Duloxetine, a serotonin norepinephrine reuptake inhibitor, can also be tried (Tsakiris et al, 2008). However, this is an off-license use of the medication that has only been licensed in several countries around the world to women who are experiencing moderate to severe incontinence. The efficacy data for men are limited.

If these treatments fail to control the incontinence and patients are still bothered, then surgical treatment is often offered, usually using an AUS, which is the gold-standard treatment, or using one

of the other options, which include the male sling and, occasionally, the ProACT balloon (see Chapter 91).

Treatment of Mixed Urinary Incontinence

Treatment of MUI is more challenging. It should be aimed at treating the most bothersome symptom. Diagnosis of the SUI component, even on urodynamics, is sometimes difficult if UII is the predominant type of incontinence. Initial treatment usually involves treating DO with antimuscarinics and even with Botox, and then repeating the urodynamics to determine if there is an SUI component.

Treatment of Other Types of Urinary Incontinence

The other types of UI are treated based on the etiology and treatment of the underlying cause.

Enuresis

Patients with high-pressure urinary retention causing nocturnal enuresis are treated by initial catheterization to relieve the pressure, followed by appropriate assessment with a view to using endoscopic surgery to resect, to vaporize, or to enucleate the prostate, or open removal of the prostate.

Nocturnal enuresis, without residual urine, may be related to the OAB. This can be treated with antimuscarinics and potentially with desmopressin in the melt formulation. It can also be related to relaxation of the pelvic floor during sleeping in patients with a neobladder following cystoprostatectomy. These patients sometimes only leak at night and treatment is usually conservative.

Postmicturition Dribble

Treatment of postmicturition dribble has not been well studied and there are no medications available that have been approved for this indication. The main form of treatment is pelvic floor muscle training with a strong pelvic squeeze at the end of voiding and also urethral milking (Paterson et al, 1997; Dorey et al, 2004). The man is asked to wait for a few seconds after passing urine to ensure that the bladder is empty. Then he must place the fingertips of one of his hands three-finger breadths behind the scrotum and apply gentle pressure in the midline and gently move the fingertips toward the base of the penis under the scrotum. The aim is to push the urine forward into the middle part of the penis. From then on, the penis is milked, squeezed, and shaken to empty any remaining urine. The process is repeated twice to ensure that no further urine remains in the urethra.

KEY POINTS: TREATMENT OF URINARY INCONTINENCE

URGENCY URINARY INCONTINENCE

- Fluid manipulation and lifestyle changes
- Bladder training and pelvic floor muscle training
- Antimuscarinics and/or β_3 agonists
- Botox
- SNS
- Augmentation cystoplasty
- Urinary diversion, for example, ileal conduit

STRESS URINARY INCONTINENCE

- Weight loss and lifestyle changes
- Pelvic floor muscle training
- Duloxetine (off-license)
- Penile clamp
- AUS (gold standard)
- Male suburethral sling
- ProACT balloon

CONCLUSION

UI in men can be related to a number of conditions. It is important to assess these patients appropriately to formulate a management plan that will help improve the patient's QoL. Depending on the etiology, initial treatment is usually conservative, and medical and surgical therapies are reserved for those who fail initial treatment and in whom the UI is affecting their QoL.

Evaluation of Women with Stress Incontinence

Evaluation of Men and Women with Lower Urinary Tract Symptoms

Evaluation of Neurogenic Lower Urinary Tract Dysfunction

Urodynamic (UDS) is the term used to describe testing and measurements of the function of the urinary tract. Today, UDS is most commonly done to assess the function of the lower urinary tract (LUT). The LUT has two essential functions: the storage of urine at low pressure and the voluntary evacuation of urine. Low-pressure storage is essential to protect the kidneys and ensure continence, and voluntary evacuation allows for the elimination of urine in socially acceptable situations without fear of leakage or overdistention. It is clear that a number of conditions and diseases affect the LUT and disrupt the storage and/or evacuation of urine. This can lead to bothersome symptoms (e.g., urinary frequency, urgency, and incontinence; slow or interrupted stream) or in some cases potentially harmful sequelae. In many cases, a precise assessment of storage and emptying is necessary to optimally treat patients. **UDS is the dynamic study of the transport, storage, and evacuation of urine. It comprises a number of tests that individually or collectively can be used to gain information about urine storage and evacuation.** UDS involves the assessment of the function and dysfunction of the urinary tract and includes the actual tests that are performed (UDS studies) and the observations during the testing (UDS observations) (Abrams et al, 1988, 2002).

The principles of UDS and the technical performance and interpretation of urodynamic studies has not changed since the 10th edition of *Campbell-Walsh Urology*. What is new is that there is new level 1 evidence regarding the value of UDS in certain clinical conditions. In addition, an American Urological Association (AUA) and Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) Urodynamic Guideline has been published (Winters et al, 2012) and the European Association of Urology (EAU) has published guidelines on neurogenic LUT dysfunction (NLUTD) (Pannek et al, 2013) and urinary incontinence (Lucas et al, 2013), both of which contain recommendations regarding UDS. **The AUA/SUFU Urodynamics Guideline findings and recommendations are “intended to assist the clinician in the appropriate selection of urodynamic tests, following evaluation and symptom characterization.”** We have incorporated the latest literature and guideline recommendations into this chapter, with emphasis on practical use and clinical utility. We will discuss the

different types of urodynamic tests and how they apply to specific conditions of the LUT.

Urodynamic principles, equipment, and performance details apply to both adults and children. We will limit our discussion of UDS in specific conditions to adults. However, several important things should be considered with regard to UDS in children. Many of the conditions for which UDS is used in children involve anatomic and neurologic abnormalities in which LUT function is variable and unpredictable. UDS is used to establish as clearly as possible the baseline situation, so that changes as a result of treatment and/or growth can be assessed and some guidance be obtained in the choice of treatment even if the result of UDS testing is not necessarily the deciding factor (Hosker et al, 2009). In the pediatric population, the aim of UDS is not only to provide precise knowledge of LUT function but also to provide an understanding of the current and future condition to the caregiver and to the patient (and his or her parents). Of course, it is still imperative that the testing should be relevant, reliable, and reproducible. The reader is referred to Chapter 136 for a more detailed discussion of specific conditions in children.

THE ROLE OF URODYNAMIC TESTING IN CLINICAL PRACTICE

UDS has been used for decades, yet level 1 evidenced-based “indications” for its use are limited. There are a number of reasons for this. It is difficult to conduct proper randomized controlled trials on UDS for conditions in which lesser levels of evidence and expert opinion strongly suggest clinical utility and in which empirical treatment is potentially harmful or even life-threatening (e.g., NLUTD). Additionally, symptoms can be caused by a number of different conditions, and it is difficult to study pure or homogeneous patient populations. Recently two trials, which are discussed later, have provided some level 1 evidence for the use of UDS before surgery in women with stress urinary incontinence (SUI) (Nager et al, 2012; van Leijssen et al, 2013). We believe that **given the current state of evidence for UDS studies, what is most important is that the**

clinician has clear-cut reasons for performing the study and that the information obtained will be used to guide treatment of the patient. Therefore it is probably more useful to describe the role of UDS in clinical practice rather than precise indications for its use.

In 2012, the AUA and SUFU produced their first guideline for UDS (Winters et al, 2012). There are also newly published guidelines from the EAU on urinary incontinence (Lucas et al, 2013) and neurogenic LUT dysfunction (NLUTD) (Pannek et al, 2013), both of which make recommendations regarding the use of UDS to assist the clinician in the appropriate selection tests after evaluation and symptom characterization. The AUA/SUFU Guideline was “intended to review the literature regarding urodynamic testing in common LUT conditions and assist clinicians in the proper selection and application of urodynamic tests, following an appropriate evaluation and symptom characterization.” The EAU Guidelines offer practical advice based mostly on expert opinion. We, like the AUA/SUFU guidelines panel, believe that UDS guidelines do not necessarily establish the standard of care, but rather should encourage compliance by practitioners with current best practices related to the condition being treated. Individual health care providers must take into account individual patient situations that can include patient willingness to be treated, variations in resources, and patient tolerances, needs, and preferences.

In practical terms, UDS is most useful when history, physical examination, and simple tests are not sufficient to make an accurate diagnosis and/or institute treatment. This has clinical applicability in the following two general scenarios:

1. To obtain information needed to make an accurate diagnosis for what condition(s) is causing the symptoms (e.g., LUT symptoms [LUTS] or urinary incontinence).
2. To determine the impact of a disease that has the potential to cause serious and irreversible damage to the upper and lower urinary tracts (e.g., neurologic conditions such as spinal cord injury, multiple sclerosis, radiation cystitis). Sometimes, profound abnormalities can be found in the relative absence of symptoms.

Rather than refer to a list of indications for UDS that often are not evidence-based at all, it is more useful for clinicians to think of how UDS should be used in a broader clinical perspective. In keeping with that theme, the role of UDS in clinical practice has been nicely summarized by Hosker and colleagues (2009) and updated by Rosier and associates (2013) for the following situations:

1. To identify or rule out factors contributing to LUTD (e.g., urinary incontinence) and assess their relative importance
2. To obtain information about other aspects of LUT function or dysfunction, whether or not expressed as a symptom or a recognizable sign
3. To allow a prediction of the possible consequences of LUTD for the upper urinary tract (see Box 73-1 for UDS findings that are risk factors for upper tract decompensation)
4. To allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment
5. To confirm the effects of intervention or understand the mode of action of a particular type of treatment for LUTD, especially a new and or experimental (preroutine) one

BOX 73-1 Urodynamic Risk Factors

The following urodynamics findings are potentially dangerous and usually require intervention to prevent upper and lower urinary tract decompensation:

1. Impaired compliance
2. Detrusor external sphincter dyssynergia (DESD)
3. Detrusor internal sphincter dyssynergia (DISD)
4. High-pressure detrusor overactivity present throughout filling
5. Elevated detrusor leak point pressure (>40 cm H₂O)
6. Poor emptying with high storage pressures

6. To understand the reasons for failure of previous treatments for urinary incontinence or for LUTD in general (after unsatisfactory treatment)

It is important to remember that UDS is only one part of the comprehensive evaluation of symptoms and LUT function and that the main goal of UDS is to reproduce the patient's symptoms, when present, and determine the cause of these symptoms by urodynamic measurements or observations. To use UDS in a practical and effective way it is important that the clinician has the proper expertise to know when and why to perform a UDS study. Despite many technical advances in the recording, processing, and printing of UDS studies, careful attention to technical details to ensure accurate collection of data remains the cornerstone of a good study. Because not all patients undergo UDS for the same reasons, the clinician should customize UDS to the patients' symptoms and condition. That means deciding on the questions to be answered before starting each study and designing that study to obtain the answers to those questions. It is important to remember that UDS is performed in an “unnatural setting” and therefore does not always duplicate real-life situations. A UDS study that does not duplicate complaints or symptoms when an abnormality is recorded is not necessarily diagnostic. In addition, failure to record an abnormality does not always rule out its existence (e.g., failure to demonstrate detrusor overactivity (DO) in a patient with urgency incontinence). Finally, not all UDS observations are clinically significant. Therefore it is important to interpret UDS studies in the context of the patient's history, including symptoms and concomitant diseases/conditions, and other information such as postvoid residual (PVR) volumes and frequency volume charts (voiding and intake diaries) when clinically applicable.

KEY POINTS: URODYNAMICS DEFINITION AND GUIDELINES

- UDS is the dynamic study of the transport, storage, and evacuation of urine.
- UDS comprises tests that individually or collectively can be used to gain information about urine storage and evacuation.
- AUA/SUFU UDS Guidelines are intended to assist the clinician to select appropriate urodynamic tests, after evaluation and symptom characterization.

FUNCTIONAL CLASSIFICATION OF VOIDING DYSFUNCTION: APPLICABILITY TO URODYNAMIC TESTING

To formulate a set of questions to be answered by a urodynamic test, an understanding of the possible causes of symptoms and the possible urodynamic manifestations of a preexisting condition is necessary. To accomplish this, a practical classification of voiding dysfunction is invaluable. The system proposed and popularized by Wein (1981) is simple and allows classification of voiding dysfunction according to urodynamic findings. Functionally, abnormalities of the LUT can be divided into the following:

1. Storage dysfunction (failure to properly store urine)
2. Emptying dysfunction (failure to empty the bladder normally)
3. Combined dysfunction (failure to store and empty)

In addition, functional abnormalities can be subclassified to the anatomic region of the LUT that is affected and how it is affected. Thus storage and emptying abnormalities can be caused by the following:

1. Bladder dysfunction
 - a. Overactive (causing failure to store)
 - b. Underactive (causing failure to empty)

2. Bladder outlet dysfunction

- a. Overactive (causing failure to empty)
- b. Underactive (causing failure to store)

3. Combined bladder and bladder outlet dysfunction

The beauty of a functional classification system is that it helps clarify treatment options for a given patient. Thus, in practical terms, the UDS evaluation should help determine if there is bladder or bladder outlet dysfunction (or both) and whether there is a storage and/or emptying problem. By providing answers to these simple questions UDS can lead to a correct diagnosis and, equally as important, institution of appropriate treatment. Obviously, an understanding of the physiology of urine storage and voiding and the pathophysiology of voiding dysfunction (see Chapter 70) is required to formulate appropriate questions to be answered by a urodynamic study. However, all too often clinicians get caught up in the intricate neurophysiologic aspects of voiding and storage dysfunction and fail to think in practical terms. One should always focus on the possible urodynamic findings in a given case and how each of the findings may ultimately affect the patient and treatment. Symptoms and/or underlying conditions or diseases will determine these potential findings.

KEY POINT: FUNCTIONAL CLASSIFICATION SYSTEM

- The functional classification system can help clarify treatment options for a given patient. Thus, in practical terms, the UDS evaluation should be performed to help determine if there is bladder or bladder outlet dysfunction (or both) and whether there is a storage and/or emptying problem.

CONDUCTING A URODYNAMIC STUDY: PATIENT AND TECHNICAL FACTORS

Preparing for a Urodynamic Study: Clinician, Patient, and Facility

Once the decision has been made to perform UDS on a particular patient it is important to consider what information is expected from the test. The simple fact that a patient has symptoms or a disorder that may affect the LUT is not sufficient to start the UDS evaluation. **A list of problems or questions that should be solved or answered by UDS should be made before any testing is performed.** All patients are not alike, and therefore each urodynamic evaluation may be different depending on the information needed to answer the questions relevant to a particular patient. **We follow these three important rules before starting the UDS evaluation (Nitti and Combs, 1998):**

1. Decide on questions to be answered before starting a study.
2. Design the study to answer these questions.
3. Customize the study as necessary.

By following these simple rules the chance of obtaining useful information from a study can be maximized. If a particular question is not answered, the study can be repeated in the same session. Most people who perform UDS regularly would concur that a urodynamic test is not always perfect in answering all important questions, but by defining the information needed before starting the study, unanswered questions can be kept to a minimum. We cannot emphasize enough that one of the most important parts of UDS is its proper performance with careful attention to technical details so that accurate interpretation is possible. It is beyond the scope of this chapter to describe the proper performance of UDS in detail; however, the reader is referred to the articles by [Schafer and colleagues \(2002\)](#) for good urodynamic practices and [Abrams and associates \(2002\)](#) for terminology. The International Continence Society (ICS) has now defined the term *urodynamic observations* to denote observations that occur during and are measured by the UDS test. To be consistent, it is recommended that all clinicians

performing and interpreting UDS use the current ICS terminology ([Abrams et al, 2002](#)). A list of common UDS terms is provided in [Box 73-2](#).

Ideally a room of suitable size should be dedicated to UDS ([Nitti and Combs, 1998](#)). This area does not have to be exclusively for UDS, but when a study is being performed, there should not be distractions from people walking into and out of the area for other reasons. A quiet private area is best. It is difficult enough to recreate a natural environment during testing without outside distractions. The room should be large enough to allow for the patient to lie down to have catheters placed and also to be able to stand and sit on a commode as necessary. Many patients undergoing urodynamic testing will have neurologic problems that limit mobility and will require assistance with positioning. This includes patients in wheelchairs. This must be considered when determining the size of the room. Centers that perform video-urodynamics (VUDS) will require a larger area to allow for x-ray equipment.

The importance of a well-trained, attentive, and supportive staff involved with the UDS study cannot be overemphasized. With that said, in general, UDS is well tolerated. **However, patients should be properly prepared and told why the test is being done, how the results may affect treatment, and what to expect during the actual UDS test.** [Scarpero and colleagues \(2005\)](#) used a questionnaire-based study to assess patient expectations of anxiety, pain, embarrassment, and apprehension before UDS and compared it to the patient's actual experience. They found that UDS was associated with minimal-to-moderate degrees of anxiety, discomfort, and embarrassment. After testing, most respondents (>90% per question) thought that the test was the same or better than expected and it was associated with an expected or less than expected level of pain and embarrassment. This did not vary between the sexes, but a higher number of younger individuals found that the test experience was worse than expected and a higher number of older individuals found that it was better than expected. Therefore younger patients may require more reassurance and attention in preparation for the procedure. Similarly, [Yokoyama and coworkers \(2005\)](#) found UDS to be quite tolerable based on a questionnaire study. Patients experienced minimal degrees of pain, embarrassment, and physical burden from UDS. On a visual analog scale of 0 to 10 (*not at all to unbearable*) in 154 consecutive patients (56% men) the mean (standard deviation) degrees of pain, embarrassment, and physical burden were 2.27 (2.53), 2.59 (2.69), and 1.76 (2.43), respectively, and 73.6% of men and 80.6% of women were willing to repeat UDS. The most common complaint after UDS was micturition pain. Urinalysis showed that 4.6% of men and 7.5% of women had leukocyturia after the investigation.

Many patients undergoing urodynamic testing will have been placed on medications that can affect bladder function (e.g., anti-muscarinics). For such patients the clinician should decide in advance what information is desired and whether the study should be done on or off medication. For example, if the goal of the study is to determine the therapeutic effect of a medication, obviously the UDS should be done with the patient on a regular dosing schedule for that medication. On the other hand, if medication was started empirically to treat symptoms and the goal of the urodynamic test is to uncover the cause of those symptoms, consideration can be given to discontinuing the medication before testing because this may give the highest yield.

COMPONENTS OF THE URODYNAMIC STUDY

Before discussing the details of the UDS test itself it is useful to be familiar with the test components. These tests within the test can be used individually or in combination depending on the information desired. For the purposes of this chapter we will discuss each component as part of the entire multichannel UDS or VUDS study. Uroflow and PVR determination are two simple, noninvasive tests that can be used to evaluate voiding function and perhaps prompt further testing. In addition, both are part of a multichannel UDS study.

BOX 73-2 Terminology for Common Urodynamic Terms and Observations According to the International Continence Society Standardization Subcommittee

The International Continence Society (ICS) has now defined the term *urodynamic observations* to denote observations that occur during and are measured by the urodynamics (UDS) test itself. To be consistent, it is recommended that all clinicians performing and interpreting UDS use the current ICS terminology (Abrams et al, 2002).

Two principal methods of urodynamic investigation exist:

Conventional urodynamic studies: Normally take place in the urodynamic laboratory involving artificial bladder filling.

Ambulatory urodynamic studies: A functional test of the lower urinary tract using natural filling and reproducing the subject's everyday activities.

The following are required of both types of studies:

Intravesical pressure: The pressure within the bladder.

Abdominal pressure: The pressure surrounding the bladder; currently it is estimated from rectal, vaginal, or extraperitoneal pressure or a bowel stoma.

Detrusor pressure: The component of intravesical pressure created by forces on the bladder wall that are both passive and active.

Filling cystometry: The method by which the pressure and volume relationship of the bladder is measured during bladder filling.

Physiologic filling rate: A filling rate less than the predicted maximum. Predicted maximum is the body weight in kilograms divided by 4 and expressed as milliliters per minute.

Nonphysiologic filling rate: A filling rate greater than the predicted maximum.

Bladder sensation during filling cystometry:

Normal bladder sensation, defined by three points noted during filling cystometry and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints.

First sensation of bladder filling: The volume at which the patient first becomes aware of the bladder filling.

First desire to void: The feeling during filling cystometry that would lead the patient to pass urine at the next convenient moment.

Strong desire to void: A persistent desire to void without the fear of leakage.

Increase that occurs at low bladder volumes and persists.

Reduced bladder sensation: Diminished sensation throughout bladder filling.

Absent bladder sensation: The individual has no bladder sensation.

Nonspecific bladder sensation: The individual is aware of bladder filling because of other sensations such as abdominal fullness or vegetative symptoms.

Bladder pain: A self-explanatory term that is abnormal.

Urgency: A sudden compelling desire to void.

Normal detrusor function: Allows bladder filling with little or no change in pressure, no involuntary contractions despite provocative maneuvers.

Detrusor overactivity: Involuntary detrusor contractions during the filling phase, spontaneous or provoked.

Phasic detrusor overactivity: A characteristic waveform that may or may not lead to urinary incontinence.

Terminal detrusor overactivity: A single involuntary detrusor contraction occurring at cystometric capacity that cannot be suppressed, resulting in incontinence with bladder emptying.

Detrusor overactivity incontinence: Incontinence related to involuntary detrusor contractions. This may be qualified according to cause.

Neurogenic detrusor overactivity: Overactivity accompanied by a neurologic condition; this term replaces the term *detrusor hyperreflexia*.

Idiopathic detrusor overactivity: Detrusor overactivity without concurrent neurologic cause. This term replaces the term *detrusor instability*.

Provocative maneuvers: Techniques used during urodynamic border to provoke detrusor overactivity.

Cystometric capacity: The bladder volume at the end of the filling cystogram when permission to void is given.

Maximum cystometric capacity: The volume at which the patient feels he or she can no longer delay micturition and has a strong desire to void.

Maximum anesthetic bladder capacity: The volume to which the bladder can be filled under deep general or spinal anesthesia. This should be qualified as to what type of anesthesia is used, the rate of filling, the length of time of filling, and the pressure to which the bladder is filled.

Normal urethral closure mechanism: This maintains a positive urethral closure pressure during bladder filling even in the presence of increased abdominal pressure.

Incompetent urethral closer mechanism: This is defined as one allowing leakage of urine in the absence of detrusor contraction.

Urethral relaxation incontinence: Leakage related to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity.

Urodynamic stress incontinence: Noted during filling cystometry and defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction. This currently replaces genuine stress incontinence.

Urethral pressure measurements:

Urethral pressure: The fluid pressure needed to just open a closed urethra.

Urethral pressure profile: A graph indicating the intraluminal pressure along the length of the urethra.

Urethral closure pressure profile: The subtraction of intravesical pressure from urethral pressure.

Maximum urethral pressure: The maximum pressure of the measured profile.

Maximum urethral closure pressure (MUCP): The maximum difference between the urethral pressure and the intravesical pressure.

Functional profile length: The length of the urethra along which the urethral pressure exceeds intravesical pressure in women.

Pressure transmission ratio: The increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in intravesical pressure.

Abdominal leak point pressure: The intravesical pressure at which urine leakage occurs because of increased abdominal pressure in the absence of a detrusor contraction.

BOX 73-2 Terminology for Common Urodynamic Terms and Observations According to the International Continence Society Standardization Subcommittee—cont'd

Detrusor leak point pressure: The lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure.

Pressure-flow studies: The method by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying.

Pressure measurements during pressure-flow studies:

Premicturition pressure: The pressure recorded immediately before the initial isovolumetric contraction.

Opening pressure: The pressure recorded at the onset of urine flow.

Opening time: The elapsed time from original rise in detrusor pressure to onset of flow.

Maximum pressure: The maximum value of the measured pressure.

Pressure at maximum flow: The lowest pressure recorded at maximum measured flow rate.

Closing pressure: The pressure measured at the end of measured flow.

Minimum voiding pressure: The minimum pressure during measurable flow.

Flow delay: The time delay between a change in bladder pressure and the corresponding change in measured flow rate.

From Abrams P, Cardozo L, Fall M, et al. The standardisation of terminology of lower urinary tract function: report from the Standardisation Subcommittee of the International Continence Society. *Neurourol Urodyn* 2002;21:167–78; and Schafer W, Abrams P, Liao L, et al. Good urodynamic practices: uroflowmetry, filling, cystometry, and pressure-flow studies. *Neurourol Urodyn* 2002;21:261–74.

PVR is an excellent assessment of bladder emptying. It can be performed by ultrasound (bladder scan) or catheterization. Elevation of PVR indicates a problem with emptying but does not indicate the reason. An elevated PVR may prompt further testing.

Uroflowmetry is measurement of the rate of urine flow over time. It is also an assessment of bladder emptying. Multiple data points can be reported from noninvasive uroflowmetry. These include the following:

- Voided volume (VV in milliliters)
- Flow rate (Q in milliliters per second)
- Maximum flow rate (Qmax in milliliters per second)
- Average flow rate (Qave in milliliters per second)
- Voiding time (total time during micturition in seconds)
- Flow time (the time during which flow occurred in seconds)
- Time to maximum flow (onset of flow to Qmax in seconds)

In addition to these objective measurements, it is also important to observe the pattern or shape of the uroflow curve. A normal uroflow curve is bell-shaped (Fig. 73-1). Uroflow curve interpretation is somewhat subjective because of difficulty in qualitatively judging a pattern (Boone and Kim, 1998). When the flow rate is reduced or the pattern is altered, this could indicate bladder (underactivity) or bladder outlet (anatomic or functional obstruction) dysfunction (see Fig. 73-1). Although certain patterns are suggestive of certain voiding dynamics (e.g., an interrupted or straining pattern with detrusor underactivity [DU], and a flattened pattern with a fixed obstruction), specific underlying abnormalities cannot be definitively identified without detrusor pressure data (see later discussion of invasive pressure-flow UDS).

Cystometry (CMG) or, more appropriately, filling CMG is the method by which the pressure/volume relationship of the bladder is measured during bladder filling. The filling phase starts when filling commences and ends when the patient and urodynamicist decide that permission to void has been given (maximum cystometric capacity). CMG can be performed by the single measurement of bladder pressure via a bladder catheter (urethral or suprapubic); however, changes in bladder pressure can represent a change in detrusor pressure (Pdet) or a change in abdominal pressure (Pabd) (see later). Therefore it is recommended that CMG be performed by measuring both the total vesical pressure (Pves) and Pabd (measured by a catheter placed in the rectum or vagina). To calculate Pdet the following equation is used (Fig. 73-2):

$$P_{det} = P_{ves} - P_{abd}$$

Electromyography (EMG) is the study of the electronic potentials produced by the depolarization of muscle membranes. In the case

of UDS, EMG measurement of the striated sphincteric muscles of the perineum is done to evaluate possible abnormalities of pelvic floor muscle function, which are often associated with LUTS and LUTD. EMG activity is measured during both filling and emptying. EMG is performed via electrodes placed in (needle electrodes) or near (surface electrodes) the muscle to be measured.

The **urethral pressure profile** (UPP) is a graph indicating the intraluminal pressure along the length of the urethra. Urethral pressure is defined as the fluid pressure needed to just open a closed urethra. UPP is obtained by withdrawal of a pressure sensor (catheter) along the length of the urethra.

Pressure-flow studies of voiding are the method by which the relationship between Pdet and urine flow rate is measured during bladder emptying (voiding). Pdet is measured as described previously with the simultaneous measurement of flow rate by uroflowmeter. The voiding phase starts when permission to void is given, or when uncontrollable voiding begins, and ends when the patient considers voiding has finished.

URODYNAMIC EQUIPMENT

Urodynamic Systems

A variety of different urodynamic systems are available today. They range in cost depending on their features and complexity. Current UDS systems are computer-based digital systems that allow for easy data storage and postprocessing of the study. In addition they allow for hardware and software upgrades as necessary. It is beyond the scope of this chapter to describe in detail the options available for UDS systems. However, it is recommended that, when choosing a system, the patient population and spectrum of diseases frequently encountered, space, convenience of operation (if a factor), and the need for data storage and processing be considered. In addition it is recommended that a multichannel system be used where channels are available to measure Pves, Pabd (and subtracted Pdet), and flow rate. Some clinicians also may desire channels for EMG and urethral pressure measurement. The UDS system and software market is constantly changing, so what is state-of-the-art today may seem outdated tomorrow. However, despite all the advances, the clinician performing the study remains the most important constant in data collection and interpretation. For the most realistic assessment, the infusant should be a liquid (e.g., normal saline or radiographic contrast) that most approximates urine. The use of gas, such as carbon dioxide, is not recommended. Many advanced urodynamic centers now perform VUDS. Adding this capability is costly, but it allows the most comprehensive study possible. In

Figure 73-1. Examples of uroflow curves. **A**, Normal bell-shaped flow curve of flow rate versus time. **B**, Flattened pattern usually indicative of obstruction. **C**, Interrupted or straining pattern, which can be seen with impaired bladder contractility, obstruction, or voiding with or by abdominal straining. (A, From Wein AJ, English WS, Whitmore KE. Office urodynamics. *Urol Clin North Am* 1988;15:609; B and C, from Boone TB, Kim YH. Uroflowmetry. In: Nitti VW, editor. *Practical urodynamics*. Philadelphia: Saunders; 1998. p. 28–51.)
